ABSTRACT

Background: The prevalence of hyperuricemia and gout has increased in recent decades. The role of dietary fructose in the development of these conditions remains unclear.

Objective: To conduct a systematic review and meta-analysis of prospective cohort studies investigating the association fructose consumption with incident gout and hyperuricemia.

Design: MEDLINE, EMBASE and the Cochrane Library were searched (through September 2015). We included prospective cohort studies that assessed fructose consumption and incident gout or hyperuricemia. 2 independent reviewers extracted relevant data and assessed study quality using the Newcastle-Ottawa Scale. We pooled natural-log transformed risk ratios (RRs) using the generic inverse variance method. Interstudy heterogeneity was assessed (Cochran Q statistic) and quantified (I^2 statistic). The overall quality of the evidence was assessed using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach.

Results: 2 studies involving 125 299 participants and 1533 cases of incident gout assessed the association between fructose consumption and incident gout over an average of 17 years of follow-up. No eligible studies assessed incident hyperuricemia as an outcome. Fructose consumption was associated with an increase in the risk of gout (RR=1.62, 95% CI 1.28 to 2.03, p<0.0001) with no evidence of interstudy heterogeneity (I^2=0%, p=0.33) when comparing the highest (>11.8% to >11.9% total energy) and lowest (<6.9% to <7.5% total energy) quantiles of consumption.

Limitations: Despite a dose–response gradient, the overall quality of evidence as assessed by GRADE was low, due to indirectness. There were only two prospective cohort studies involving predominantly white health professionals that assessed incident gout, and none assessed hyperuricemia.

Conclusions: Fructose consumption was associated with an increased risk of developing gout in predominantly white health professionals. More prospective studies are necessary to understand

Strengths and limitations of this study

- This systematic review and meta-analysis assessed the overall quality of the evidence using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach.
- Large prospective cohort studies that were of high quality and had a long duration of follow-up were included.
- The pooled results showed good consistency (low between-study heterogeneity) and evidence of a dose–response gradient.
- Only two prospective cohort studies with low external generalisability were available for inclusion.
- The observational design of the prospective cohort studies did not allow for causal inferences to be drawn.

better the role of fructose and its food sources in the development of gout and hyperuricemia.

Protocol registration number: NCT01608620.

INTRODUCTION

Gout is a systemic rheumatic condition characterised by monosodium urate crystal deposition and accumulation around joints. Individuals with gout often experience acute and recurring attacks of arthritis that can affect several joints.[1] Hyperuricemia or excessive circulating concentrations of urate, the final product of purine metabolism, is a major risk factor for gout and plays a major role in the pathogenesis of this condition.[2] Chronic hyperuricemia and gout also represent potential risk factors for cardiovascular disease (CVD).[3] According to the National Health and Nutritional Examination Survey 2007–2008, hyperuricemia affects >20% of

the US population, while ~4% of American adults have gout.[4] The prevalence of hyperuricemia and gout has increased in recent decades,[4–6] suggesting potential environmental triggers. Several lifestyle and dietary factors have been implicated in the development of these conditions, including elevated body mass index (BMI),[7] alcohol consumption[8] and high dietary intakes of meat and seafood.[9] [10] Recent research has also implicated fructose intake in the pathogenesis of hyperuricemia and gout.[11] [12]

Fructose is a monosaccharide found commonly in plants. It is also a major constituent of high-fructose corn syrup (HFCS) in sugar-sweetened beverages (SSBs).[13] Ecological evidence has shown that the increasing prevalence of hyperuricemia and gout in developed countries has paralleled the increase in consumption of total fructose and HFCS.[14] The phosphorylation of fructose, unlike the monosaccharide glucose, is understood to facilitate ATP depletion and result in an elevation of circulating uric acid levels.[11] [15] [16] Animal studies and select trials of acute ingestion of fructose-sweetened beverages have shown that fructose can lead to higher blood concentrations of uric acid.[17] [18] However, a meta-analysis of isocaloric substitution trials did not support this association between fructose and serum uric acid.[19] The role of fructose from all dietary sources as a risk factor for incident hyperuricemia and ultimately gout, therefore, remains unclear. Furthermore, there is a notable lack of meta-analyses of prospective studies assessing the role of dietary fructose in the development of disorders of purine metabolism. The objective of this study was to conduct a systematic review and meta-analysis of prospective cohort studies investigating total fructose consumption and its association with incident hyperuricemia and gout.

METHODS

This meta-analysis was conducted in accordance with the Cochrane handbook for systematic reviews of interventions[20] and reported following the Meta-analysis of Observational Studies in Epidemiology (MOOSE) guidelines.[21] The study protocol was registered at ClinicalTrials. gov (NCT01608620).

Study selection

We performed a comprehensive search of MEDLINE, EMBASE and the Cochrane Library databases from conception through 22 September 2015. The following search terms were used: 'fructose', 'sucrose', 'sugar', 'honey', 'HFCS', 'gout', 'hyperuricemia' and 'uric acid'. No language restrictions were imposed on the search. The complete search strategy is reported in online supplementary table S1. The electronic search was supplemented by a manual review of article reference lists. Abstracts were considered, and authors were contacted for missing information. We only included prospective cohort studies which assessed the association between total dietary fructose intake and incident hyperuricemia or

gout. Studies were considered eligible if cases of gout were ascertained using self-report of a physician diagnosis, while the assessment of hyperuricemia required serum uric acid measurements above study-specific predefined thresholds.

Data extraction

Studies were reviewed and excluded based on an evaluation of titles and abstracts. Articles that passed this initial screening were then reviewed in full by two independent reviewers (JJ and SR). The following data were extracted from each using a standardised *proforma*: authorship, year of publication, cohort name, country, sample size, participant characteristics, duration of follow-up, method of dietary assessment, fructose exposure levels, number of incident hyperuricemia/gout cases, covariates included in statistical models and risk ratios (RRs) of hyperuricemia or gout per quantile of fructose intake with 95% CIs.

Study quality

Study quality was assessed using the Newcastle-Ottawa Scale (NOS) for Cohort Studies. The NOS for Cohort Studies is a rating scale where points are awarded to studies based on cohort selection, comparability of groups and assessment of outcomes.[22] Any given study can have a maximum of nine points. In this analysis, studies that received ≥6 points were considered of high quality. Differences in grading between reviewers were resolved by consensus.

Grading of Recommendations Assessment, Development and Evaluation

The Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach was used to assess the overall quality and strength of evidence.[23–35] By this approach, the quality of the totality of evidence can be graded as 'very low', 'low', 'moderate' or 'high'. Evidence derived from observational studies receive an initial grade of 'low', while evidence derived from randomised trials receive an initial grade of 'high'.[25] Scores can be either upgraded or downgraded depending on a number of factors. Scores for observational analyses can be upgraded for a large magnitude of effect (RR>2 or RR<0.5 in the absence of plausible confounders), dose–response gradient or reasonable evidence of attenuation of the pooled effect estimate by confounders.[31] Conversely, scores can be downgraded for risk of bias (weight of studies show risk of bias as assessed by low NOS <6),[26] inconsistency (substantial unexplained inter-study heterogeneity), $I^2 > 50\%$,[29] indirectness (presence of factors that limit the generalisability of the results),[30] imprecision in the pooled risk estimate (the 95% CI for risk estimates are wide or cross a minimally important difference of 10% for benefit or harm (RR 0.9–1.1)),[28] and publication bias (evidence of small-study effects).[27]

Statistical analysis

Data analysis was carried out using Review Manager (RevMan, V.5.3; The Nordic Cochrane Centre, The

Cochrane Collaboration). RRs of extreme quantiles of fructose intake for incident hyperuricemia/gout were natural-log transformed and pooled using the generic inverse variance method.[36] Although random-effects models are preferred to fixed effects models because of their conservative nature in the presence of residual interstudy heterogeneity, we used fixed effects models as there were too few studies to estimate τ^2 reliably. Interstudy heterogeneity was assessed and quantified using the Cochran Q and I^2 statistics, respectively.[37] The I^2 statistic represents the percentage of total variation across studies that is due to between-study heterogeneity, and $I^2 \geq 50\%$ was considered evidence for substantial heterogeneity.[20] We could not explore sources of heterogeneity by sensitivity analyses or a priori subgroup analyses owing to too few studies. Publication bias also could not be assessed owing to too few studies.

RESULTS
Search results
Results of the systematic search and article selection process are shown in figure 1. Of the 2195 studies initially identified in the literature search, 2171 were excluded on the basis of title and abstract review. The remaining 24 articles were reviewed in full, and 22 were subsequently excluded. A total of two prospective cohort studies were included in this analysis.[38 39] Both of these studies pertained to fructose intake and incident gout. We did not identify any prospective studies that assessed total fructose intake and its association with incident hyperuricemia.

Study characteristics
The characteristics of the two prospective cohort studies included in this analysis are presented in table 1. Both studies investigated cohorts based in the USA and comprised of older, predominantly white (91% and 95%), health professionals. Choi et al[38] consisted of 46 393 male dentists, optometrists, osteopaths, pharmacists and veterinarians; aged 40–75, from the Health Professionals Follow-up Study. Choi et al[39] investigated a cohort of 78 906 female nurses aged 30–55, from the Nurses' Health Study. The follow-up rate for both cohorts exceeded 90%. The women's cohort had a follow-up duration of 22 years,[39] while the male cohort was followed for 12 years.[38] Both studies received six points on the NOS, indicating that they were of high quality. All 125 299 participants across both studies were free of gout at baseline, and a total of 1533 confirmed cases of incident gout (755 men, 778 women) were identified.

Methods for collecting dietary and health information were similar between studies. Validated food frequency questionnaires (FFQs) of over 130 different foods and beverages were completed every 4 years. Corresponding nutrient values were derived from US Department of Agriculture Sources and supplemented by manufacturers. Total fructose intake, defined as fructose plus half the intake of sucrose, was assessed in both studies. Median fructose intake was ~7.2% of total energy in the lowest quantiles of intake and ~11.9% of total energy in the highest quantiles of intake.[38 39] In the prospective study of the Health Professionals Follow-up Study, the main dietary sources of total monosaccharide fructose were orange juice (15.9%), SSBs (15.5%), apples (14.5%), raisins (5.2%) and oranges (3.2%).[38]

Information regarding weight, medications and medical conditions (including gout) was collected at baseline and every 2 years following for the duration of both studies. Participants who reported physician-diagnosed incident gout were sent a supplementary questionnaire based on the American College of Rheumatology gout survey criteria.[40] To meet the end point of the study, participants needed ≥6 symptoms out of a possible 11. The response rate of the supplementary survey was ~80% for both cohorts. Both studies adjusted for the critical confounders of age, BMI, total energy intake and alcohol consumption (each study was conducted in a single sex, so adjustment for sex was not necessary). Additional adjustments were made for diuretic use, history of hypertension, history of renal failure, menopause status, use of hormone therapy; caffeine intake and total vitamin C; as well as the percentage of energy from total carbohydrates.[38 39]

Funding sources were assessed for all of the included prospective cohort studies. All reported funding from agency alone.[38 39]

Total fructose intake on incident gout
Figure 2 depicts the relationship between total fructose intake and incident gout. We identified a significant overall association between fructose intake and increased risk of incident gout with a pooled RR of 1.62 (95% CI 1.28 to 2.03) with no evidence of significant interstudy heterogeneity ($I^2 = 0\%$, p=0.33). The pooled risk estimates came from the most-adjusted models including the adjustment for energy from total carbohydrate intake.[38 39] This model allows for the effects of fructose compared with isocaloric exchange for other carbohydrates to be estimated. Both studies included in our analysis also presented results adjusted for energy from non-fructose carbohydrate and total protein to facilitate the comparison of isocaloric substitution of fructose for fat. This model resulted in more modest effect estimates (RR 1.34, 95% CI 1.05 to 1.72) (see online supplementary figure S1). Pooled analysis of the least-adjusted models (adjusted for age, total energy intake, BMI and alcohol consumption in both studies) did not result in a significant association between fructose intake and gout (RR 1.10, 95% CI 0.88 to 1.39) (see online supplementary figure S2).

Total fructose intake on incident hyperuricemia
The lack of prospective studies investigating the association between total fructose intake and incident hyperuricemia yielded by our strategy precluded testing the effect of total fructose intake on incident hyperuricemia.

Figure 1 Summary of evidence search and selection. Flow of the literature search for the effect of fructose intake on incident gout and hyperuricemia. Of the 2195 studies initially identified, 2171 were excluded on the basis of title and abstract review. The remaining 24 studies were reviewed in full. A total of two prospective cohort studies met inclusion criteria and qualified for further analysis.

Study quality
Online supplementary table S2 shows the NOS for assessing the quality of cohort studies. All studies were considered to be high quality (NOS≥6).

GRADE assessment
The overall strength and quality of the evidence for the effect of fructose intake on incident gout was assessed by GRADE. Despite grading up for an observed dose–response gradient in the studies, evidence of serious indirectness resulted in the evidence being downgraded to low quality, the default level for observational studies (see online supplementary table S3).

DISCUSSION
Statement of principle findings
We present the results of a systematic review and meta-analysis of prospective cohort studies investigating the association between total fructose intake and risk of developing hyperuricemia and gout. We identified a total of two prospective studies that assessed the relationship between fructose and gout[38 39] and no prospective studies pertaining to fructose and hyperuricemia. The two studies that assessed gout included a total of 125 299 participants free of gout at baseline, and 1533 identified cases of incident gout over an average of 17 years of follow-up. The results of our pooled analysis indicated that total fructose consumption was positively associated with an increased risk of developing gout by 62% when comparing extreme quantiles of fructose intake.

Strengths and weaknesses of the study
There are many strengths of our analysis pertaining to fructose and gout. The studies that were included were relatively large (125 299 participants and 1533 cases of incident gout), and both had follow-up durations in

Table 1 Characteristics of prospective cohort studies investigating total dietary fructose intake and incident gout

Study, year	Country	Participants	Age range	Duration	Dietary assessment	Divisions	Total incidence	Exposure range (total fructose)	Method of outcome measure	Funding source*	Adjustments
Choi et al,[38] 2008 Males	USA	46 393 M	40–75	12 years	Food frequency questionnaire (repeated every 4 years)	Quintiles	755	<6.9–>11.8 (% energy)	Self-report and supplementary questionnaire	Agency	Age, total energy intake, BMI, diuretic use, hypertension, renal failure, alcohol, vitamin C, percentage of energy from carbohydrates
Choi et al,[39] 2010 Females	USA	78 906 F	30–55	22 years	Food frequency questionnaire (repeated every 4 years)	Quintiles	778	<7.5–>11.9 (% energy)	Self-report and supplementary questionnaire	Agency	Age, total energy intake, BMI, menopause, hormone therapy, diuretic use, hypertension, alcohol, vitamin C, caffeine, percentage of energy from carbohydrates

excess of 10 years (12 and 22 years). The methodologies of these two studies, including the validated FFQ used for dietary assessment and the evaluation of incident gout, were remarkably similar, and there was no evidence of interstudy heterogeneity. In both studies, repeated administration of FFQs facilitated the analyses of long-term intakes of fructose, not simply diets at baseline. Furthermore, both studies included in the analysis of gout had NOS scores ≥6, indicating that they were of high quality. We also assessed the overall strength of evidence from both studies combined using the GRADE approach. However, there are many notable limitations. We were unable to test the pooled relationship between fructose intake and incident hyperuricemia due to the lack of any prospective studies investigating this association. With regard to fructose and incident gout, we only identified two prospective studies. This meant that we were unable to assess publication bias or perform sensitivity, a priori subgroup and dose–response analyses using the pooled data. Furthermore, although the number of participants included in both studies were relatively large, both cohorts were recruited in the USA, meaning that our analysis has low generalisability to other populations. Indeed, various genetic risk factors for gout have been identified[41] with some ethnic groups particularly susceptible to gout,[6] therefore, the results might not apply to other populations. Finally, although both studies included in this analysis adjusted for a number of potentially important confounders, the observational design of these studies precludes the inference of causation due to the possibility of residual confounders that remain unaccounted.

Findings in relation to other studies

The results of our meta-analysis support the notion that elevated fructose intake is a risk factor for the development of gout. A recent cross-sectional analysis identified a link between intake of SSBs and prevalent gout,[42] and a systematic review[43] of risk factors associated with gout identified fructose intake among other established dietary risk factors including alcohol, meat and seafood consumption. Dietary factors associated with a lower risk of gout include dairy, folate and coffee intake.[43] Both studies included in our meta-analysis identified a significant association between SSB consumption and increased risk of gout while similar associations were not observed for diet soft drink consumption.[38 39]

The prevalence of gout has been found to be significantly higher in men than women in many diverse populations.[44–46] Of the two studies included in our analysis of fructose and gout, one was conducted in men from the Health Professionals Follow-up Study,[38] and the other was carried out in women from the Nurses' Health Study.[39] In agreement with worldwide prevalence estimates, men in the Health Professionals Follow-up Study developed gout at a higher rate than women from the Nurses' Health Study. This potentially contributed to the lower effect size observed in the analysis of the

Study, year [Reference]	Participants	Cases	Weight	Risk Ratio [95% CI]

Heterogeneity: Tau^2 = 0.00; Chi^2 = 0.95; df = 1 (p=0.33); I^2 = 0%
Overall association: Z = 4.10 (p < 0.0001)
Figure 2 Fructose intake and the relative risk of gout. Forest plot of prospective cohort studies investigating the relationship between total fructose intake and incident gout. Estimates from most-adjusted multivariate models accounting for percentage of energy from total carbohydrates were used. The diamond represents the pooled effect estimate. Interstudy heterogeneity was tested using Cochran Q statistic and quantified using the I^2 statistic (I$^2 \geq$50% indicative of significant heterogeneity). All results are presented as risk ratios (RR) with 95% CIs.

Nurses' Health Study despite a larger sample size and similar levels of fructose intake compared to the Health Professional Follow-up Study analysis. Although the exact mechanisms that result in differences in the rates of developing gout between the sexes have not yet been fully elucidated, the protective and uricosuric effects of female sex hormones are thought to play a role.[47][48]

Hyperuricemia is a major risk factor for gout and is understood to be instrumental in its development.[1] Emerging evidence has also implicated hyperuricemia in the development of the metabolic syndrome, hypertension and CVD[3] although these associations have not been consistently reported in studies that include only hyperuricemic individuals without gout.[49][50] We found no prospective studies investigating fructose intake and incident hyperuricemia to support the observed association between fructose and gout. Some cross-sectional analyses and clinical trials have supported the association between HFCS-sweetened beverage intake and increased levels of circulating uric acid;[51–54] however, analysis of NHANES data did not support the link between fructose intake and increased risk of hyperuricemia.[55] Furthermore, prospective evidence has shown that intake of SSBs, which is known to be a large contributor to total fructose intake in western populations,[56] is not associated with an increased risk of incident hyperuricemia.[52] These inconsistent findings highlight the need for more long-term prospective studies investigating fructose intake from all sources in order to gain a better understanding of the effects of fructose intake on risk of hyperuricemia.

Meaning of study: possible explanations and implications for clinicians and policymakers

Mechanistically, the phosphorylation of fructose is thought to lead to ATP depletion and the subsequent accumulation of AMP.[57] The lack of free phosphate results in the conversion of AMP to IMP, a uric acid precursor, by AMP deaminase.[39] High fructose levels and this associated decrease in ATP have been shown to lead to a compensatory effect of increasing purine nucleotide synthesis,[15] which can subsequently lead to the further overproduction of uric acid in the presence of additional fructose. Additionally, fructose-induced hyperinsulinemia and insulin resistance[39][58] may lead to higher levels of circulating uric acid through the reduction of uric acid excretion.[59] Results of our pooled analysis suggest that fructose may indeed act as a risk factor for the development of gout; however, the lack of prospective studies assessing hyperuricemia as an outcome limits our ability to attribute this association with gout to the mechanism proposed above. It remains possible that fructose intake increases the risk of developing gout through undetermined mechanisms independent of any effects on serum urate levels, although this is unlikely given the link between fructose and uric acid production[57] and the established role of elevated serum urate in the development of gout.[2]

Current dietary guidelines recommend a reduction in added or free sugars that include fructose intake (especially from SSBs) while also not discouraging the consumption of sugars from whole fruits and vegetables.[60] While SSBs represent the largest contributor to total fructose intake in the USA, fruits and fruit products are also a significant contributor.[56] Furthermore, the 2012 American College of Rheumatology Guidelines for Management of Gout recommends limited consumption of HFCS-sweetened soft drinks and energy drinks but does not mention whether fructose from other sources should be limited.[61] It is clear that more prospective research investigating the effects of fructose intake and important food sources of fructose (SSBs, fruits and fruit products, grain-based products, dairy products, etc) on incident gout and hyperuricemia are necessary to better inform policymakers as they develop improved dietary guidelines for the management and prevention of these chronic conditions.

CONCLUSIONS

Our systematic review and meta-analysis of prospective cohort studies supports the association between fructose intake and increased risk of developing gout. The strength of evidence for the association between fructose consumption and risk of gout was low, as assessed by GRADE. It means that further research is likely to have a

significant impact on our confidence in the effect estimate and is likely to change the estimate.[25] Indeed, only two studies involving predominantly white health professionals were included in our analysis. Nevertheless, our results are consistent with a growing body of literature implicating fructose as a risk factor for developing gout. We were unable to identify any prospective studies investigating the effects of fructose intake on risk of developing hyperuricemia. Given that gout is on the rise and has recently been shown to affect ∼4% of the American population,[4 5] it is crucial that the dietary factors that may confer risk of developing gout are fully elucidated and understood. It is, therefore, imperative that more prospective studies assess the intake of fructose and its food sources in relation to gout and hyperuricemia in diverse populations to determine if and, ultimately, to what extent fructose may mediate the risk of hyperuricemia and gout.
