ABSTRACT

Objective: The Mediterranean diet has been promoted as a healthy dietary pattern but, whether the Mediterranean diet may help to prevent hepatic steatosis is not clear. This study aimed to evaluate the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis.

Design: Population-based prospective cohort study.

Setting: The Swiss CoLaus study.

Participants: We evaluated 2288 adults (65.4% women, aged 55.8 ± 10.0 years) without hepatic steatosis at first follow-up in 2009-2012. Adherence to the Mediterranean diet was scaled as the Mediterranean diet score (MDS) based on the Mediterranean-diet Pyramid ascertained with responses to food-frequency questionnaires.

Outcome measures: New onset of hepatic steatosis was ascertained by two indices separately: the fatty liver index (FLI, ≥ 60 points) and the non-alcoholic fatty liver disease (NAFLD) score (≥ 0.640 points). Prospective associations between adherence to the Mediterranean diet and risk of hepatic steatosis were quantified using Poisson regression.

Results: During a mean 5.3-years of follow-up, hepatic steatosis was ascertained in 153 (6.7%) participants by FLI criteria and in 208 (9.1%) by NAFLD-score. After multivariable adjustment, higher adherence to MDS was associated with lower risk of hepatic steatosis based on FLI: risk ratio (95% confidence interval) 0.84 (0.73, 0.96) per one standard deviation of MDS; 0.85 (0.73, 0.99) adjusted for BMI; and 0.85 (0.71, 1.02) adjusted for both BMI and waist circumference. When using NAFLD-score, no significant association was found between MDS and risk of hepatic steatosis [0.95 (0.83, 1.09)].

Conclusion: A potential role of the Mediterranean diet in the prevention of hepatic steatosis is suggested by the inverse association observed between adherence to the Mediterranean diet and incidence of hepatic steatosis based on the FLI. The inconsistency of this association

when hepatic steatosis was assessed by NAFLD-score points to the need for accurate population-level assessment of fatty liver and its physiologic markers.

Keywords: Mediterranean diet; hepatic steatosis; fatty liver disease; prospective study.

For peer review only

STRENGTHS AND LIMITATION OF THE STUDY

- This study had the benefit of a relatively large sample size and an average of 5.3 years of follow-up.
- We applied a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean population.
- Our ascertainment of hepatic steatosis was based on two indices that has been validated for use in large epidemiological studies.
- The findings highlight the need for further research with more accurate measures of hepatic steatosis.

INTRODUCTION

Hepatic steatosis is the most common cause of liver disease [1]. In westernized countries, hepatic steatosis affects up to 34% of the general population and up to 74% of obese individuals, depending on the definition used [2–4]. Hepatic steatosis—fat content of more than 5% of liver volume—is the first recognizable stage of non-alcoholic fatty liver disease (NAFLD) [1]. Hepatic steatosis, particularly NAFLD, may progress to end-stage liver disease including fibrosis, cirrhosis, and hepatocellular carcinoma [5]. Moreover, as hepatic steatosis increases the risk of metabolic syndrome, type 2 diabetes, and cardiovascular disease (CVD), its prevention is of public health importance [6]. An unhealthy dietary pattern remains one of the primary targets of lifestyle modification for the prevention and management of hepatic steatosis and NAFLD [7,8].

The Mediterranean diet has been recently recommended for treatment of NAFLD [9]; however, evidence regarding prevention of hepatic steatosis development is sparse [10]. Adherence to the Mediterranean diet has been reported to have a beneficial impact on risks of CVD [11,12], type 2 diabetes [13], and metabolic syndrome [14]. Trial evidence demonstrated the potential benefits of the Mediterranean diet against progress of hepatic steatosis focusing on individuals with existing hepatic steatosis, either alone [15–20] or associated with metabolic risk factors such as obesity or diabetes [20–23]. Research among those without clinically manifest hepatic steatosis is restricted to observational evidence, reporting an inverse association that greater adherence to a Mediterranean diet is associated with lower prevalence of hepatic steatosis [24,25]. However, the cross-sectional design of these studies limits inference for causal associations and can be used mainly for hypothesis generation. Relevant longitudinal evidence for the primary prevention of hepatic steatosis or NAFLD has been reported only by the Framingham Heart Study, with a significant inverse

association of adherence to the Mediterranean diet with risk of hepatic steatosis in 1521 adults over 6 years of follow-up [26], but evidence is lacking in Europe.

Given the limited evidence from population-based epidemiological studies thus far, we aimed to investigate the prospective association of adherence to the Mediterranean diet with the risk of developing hepatic steatosis. We hypothesized that greater adherence to the Mediterranean diet would reduce the risk of hepatic steatosis.

METHODS

Study population

We evaluated participants in the CoLaus study, an ongoing population-based cohort investigating the clinical, biological, and genetic determinants of CVD in the city of Lausanne, Switzerland [27]. Inclusion criteria of the recruitment were adults of European origin, aged 35 to 75 years [27]. There were three study phases: baseline recruitment in 2003-2006 (n=6733), the first follow-up in 2009-2012 (n=5064), and the second follow-up in 2014-2017 (n=4881). We conducted dietary assessment at the first follow-up and therefore considered the first follow-up as the study baseline. Fatty liver index (FLI) and NAFLD-score, two indices of hepatic steatosis, were available at baseline [25]. If participants met the joint criterion of $FLI \geq 60$ or $NAFLD\text{-score} \geq -0.640$ at baseline, we excluded them as prevalent cases (see below) (n=2036). We also excluded participants with missing information on diet, outcome, and covariates (n=740) (**Figure S1**).

Dietary assessment

Participants completed a self-administered, 97-item, semi-quantitative food frequency questionnaire (FFQ) about their habitual dietary intake over the last four weeks [28], the validity of which had been assessed in canton Geneva against 24-hour recalls [28,29]. For

each item, participants were instructed to report consumption frequencies by selecting one of the seven frequency options from “less than once during the last 4 weeks” to “2 or more times per day” and by selecting a usual serving size (smaller, equal, or bigger to a reference size).

Mediterranean diet scores

We derived the pyramid-based Mediterranean diet score (MDS) as a measure of adherence to the Mediterranean diet from responses to the FFQ as we conducted previously [25]. This MDS is based on the Mediterranean Dietary Pyramid proposed by the Mediterranean Diet Foundation for both Mediterranean and non-Mediterranean countries and accounting for the traditional Mediterranean diet, contemporary lifestyle, and food environment [30]. We have previously reported that this MDS scoring algorithm predicted CVD incidence [31], as well as the prevalence of hepatic steatosis [25] in non-Mediterranean populations. Briefly, a continuous score of 0 to 1 was assigned for each recommended level of the 15 components of the pyramid (vegetables, legumes, and fish as healthy items; red meat, processed meat, potato, and sweets as unhealthy items; and fruits, nuts, cereals, eggs, dairy, white meat, and alcoholic beverages as items for which moderate consumption was recommended). The resulting MDS ranges between 0 and 15 on a continuous scale. The MDS calculation was adjusted to an energy intake of 2000 kcal/d (8.37 MJ/day) by applying a regression-residual technique for energy adjustment to each food group variable [31,32].

Ascertainment of hepatic steatosis

Two indices of hepatic steatosis were evaluated: fatty liver index (FLI) [33] and NAFLD liver fat score [34]. FLI was calculated based on a logistic function including body-mass index (BMI), waist circumference, fasting triglycerides, and gamma-glutamyl transferase (GGT) levels as follows:

$$FLI = 1 / (1 + e^{-(0.953 \times \ln(\text{triglycerides}) + 0.139 \times \text{BMI} + 0.718 \times \ln(\text{GGT}) + 0.053 \times \text{waist circumference} - 15.745)})$$

FLI×100 ranges from 0 to 100. Presence of hepatic steatosis was defined by $FLI \geq 60$, a value with a sensitivity of 61% and a specificity of 86% [33]. FLI was tested previously in comparison to ultrasonography with an area under the receiver operating characteristic curve of 0.78 (OR 95% CI: 0.77, 0.83) [35].

The NAFLD-score was calculated based on an algorithm including a logistic function with the presence of metabolic syndrome defined by criteria of International Diabetes Federation [36], presence of type 2 diabetes, and fasting concentrations of insulin, aspartate-aminotransferase (AST), and the AST/ alanine transaminase (ALT) ratio:

$$\begin{aligned} \text{NAFLD-score} = & -2.89 + 1.18 \times \text{metabolic syndrome (yes/no)} + 0.45 \times \text{type 2 diabetes (yes /no)} + 0.15 \\ & \times \text{fasting-insulin (mU/L)} + 0.04 \times \text{fasting-AST (U/L)} - 0.94 \times \text{AST/ALT} \end{aligned}$$

Presence of hepatic steatosis was defined by a NAFLD-score ≥ -0.640 , a value with a sensitivity of 86% and a specificity of 71%, when compared to proton magnetic resonance imaging [34].

Assessment of covariates at baseline

Sociodemographic, lifestyle and health characteristics were collected by self-administered questionnaires. Age, sex, marital status, occupational status, and educational level were included as indicators of sociodemographic condition. Smoking status was classified as ‘never’, ‘former’, and ‘current’. Alcohol consumption was assessed by the number of alcoholic beverage units consumed in the past week and further categorized as ‘abstainers’ (0 unit/week), ‘moderate’ (1–21 units/week for men, 1–14 for women), and ‘heavy’ (>21 units/week for men, >14 for women) drinkers (one unit corresponds to 8 g of alcohol). Physical activity was assessed with a self-administered quantitative physical activity

frequency questionnaire [37]. Health characteristics included presence of metabolic syndrome and family history of diabetes. Anthropometric and blood pressure measurements were obtained using standard procedures and equipment as previously described [27]. Plasma triglycerides, high-density lipoprotein cholesterol, and glucose were measured using standard enzymatic methods and ALT, AST, and GGT were measured using reference methods as standardized by the International Federation of Clinical Chemistry.

Statistical analysis

Statistical analyses were performed using Stata (version 15; StataCorp, College Station, TX, USA) with a two-sided test with $\alpha=0.05$. Descriptive statistics were obtained in the participants included in this study in comparison to those excluded from this study. Cohen's kappa statistics were calculated to assess the agreement between the FLI and NAFLD-score.

MDS as a measure of adherence to the Mediterranean diet was evaluated both categorically (quintiles) and continuously scaled as one SD unit. The association of MDS with the risk of hepatic steatosis was assessed using multivariable-adjusted Poisson regression models with robust standard errors and estimating risk ratios (RRs) and 95% confidence intervals (CIs). Models were adjusted for age, sex, marital status, occupational status, educational level, smoking status, energy intake, total energy expenditure, and date of dietary assessment (to adjust for seasonality). We further adjusted for BMI and waist circumference as potential confounders or factors on the causal pathway to assess the possible impact of overall and central adiposity on the association of the Mediterranean diet and hepatic steatosis.

Additionally, we also adjusted for changes in BMI categories between baseline and follow-up; for alcohol consumption (units/week); for clinical variables of metabolic risk

[blood pressure >130/85 mm Hg (yes/no), triglycerides >1.7 mmol/L (yes/no), high-density lipoprotein level <1.29 mmol/L for men and <1.03 mmol/L for women (yes/no), and glucose level \geq 5.6 mmol/L (yes/no)] [36]; and for family history of diabetes and metabolic syndrome (only for FLI) to examine their influence on the association of interest.

Possible interactions between MDS and age, sex, BMI, and alcohol consumption were tested using the Wald test. Several sensitivity analyses were conducted to examine the robustness of the observed findings. First, to assess the role of alcohol consumption (as alcohol is a risk factor for fatty liver accumulation), we excluded the alcohol component from the MDS, while adjusting for alcohol consumption as a covariate. We took the same approaches for the other MDS components to assess the impact of each component on the observed associations. Second, we conducted separate analyses after excluding participants with BMI \geq 30 kg/m²; implausible energy intake (<500 or >3500 kcal/day in women and <800 or >4000 kcal/day in men); excessive alcohol consumption; prevalent diabetes (defined as glycated haemoglobin \geq 48 mmol/mol, or fasting plasma glucose \geq 7.0 mmol/L, or use of hypoglycaemic drugs or insulin); or probable secondary causes of hepatic steatosis such as hepatitis B or C, HIV, hepatotoxic, or autoimmune disease medications. We evaluated the robustness of the results to an alternative definition of prevalent hepatic steatosis. While we excluded participants with prevalent hepatic steatosis using the specified cut-offs of FLI or NAFLD-score in the primary analysis, we used each of the two indices separately in sensitivity analyses, whereby we evaluated 2652 adults in longitudinal analysis based on FLI; and 2568 adults, based on NAFLD. Finally, we used more restrictive cutpoints and excluded participants with NAFLD-score \geq -0.640 or with FLI >30.

In a post-hoc analysis pertaining to sensitivity of the results to model covariates and for better understanding of potential mechanisms, longitudinal associations of MDS with follow-up measures of log-transformed GGT, ALT, and AST levels and with changes in BMI

and waist circumference from baseline to follow-up were examined using multivariable-adjusted linear regression. These results were expressed as β coefficient (95% CIs) for changes in each measure per 1-SD difference in MDS.

RESULTS

Participant characteristics

Of the initial 5064 participants, 2776 (54.8%) were excluded, leaving 2288 participants (65.4% women; 55.8±10.0 years) for analysis. Participants included were more likely to be women, show higher sociodemographic characteristics and lower BMI, waist circumference, liver enzymes, or prevalence of metabolic syndrome in comparison to excluded individuals (**Table S1**). Being in the highest quintile of MDS was higher among women compared to men, positively correlated with sociodemographic characteristics, and negatively correlated with being current smokers, heavy alcohol drinkers, and with BMI, waist circumference, GGT, and TG (**Table 1**).

Adherence to the Mediterranean diet and risk of hepatic steatosis

After a mean 5.3 (SD: 0.5) years of follow-up, there were 153 (6.7%) and 208 (9.1%) participants with hepatic steatosis based on FLI and NAFLD-score, respectively (**Table S2**). Case identification by FLI and NAFLD-score was modestly concordant (kappa=0.60). Multivariable-adjusted analysis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on FLI ($p_{\text{trend}} < 0.006$) with RR (95% CI) comparing the top to the bottom category of 0.50 (0.28, 0.91). The inverse associations across quintiles of MDS weakened after adjustment for BMI ($p_{\text{trend}} = 0.031$) or both BMI and waist circumference ($p_{\text{trend}} = 0.034$) (**Table 2**): RR (95% CI)=0.61 (0.34, 1.09) and 0.60 (0.34, 1.08), respectively. In analyses using MDS as a continuous variable, the inverse association with risk of hepatic

steatosis based on FLI [RR 0.84 (0.73, 0.96) per one SD of MDS] remained unchanged but getting imprecise after adjustment for BMI [RR 0.85 (0.73, 0.99)] and adjustment for both BMI and waist circumference [0.85 (0.71, 1.02)]. In sensitivity analysis, the magnitude of the inverse associations little changed after further adjustment for alcohol consumption, presence of metabolic syndrome, changes in BMI categories or clinical variables (medication use or prevalent diseases) (**Table S3**), while adjustment for BMI and clinical variables increased standard errors.

Conversely, there was no association between MDS and the risk of hepatic steatosis defined by NAFLD-score criteria, with RRs (95% CIs) ranging from 0.93 (0.82, 1.05) to 1.00 (0.86, 1.17) over different regression models (**Table 2** and **Table S3**).

Interaction and sensitivity analyses

No significant interactions were found between MDS and age, sex, BMI, or alcohol consumption on risk of hepatic steatosis ($p_{\text{interaction}} > 0.05$; results not shown). The contribution of each component of the MDS on risk of hepatic steatosis was assessed by sequential subtraction of components from the score (**Figure 1**). Excluding the components of the MDS did not substantially affect the inverse associations with hepatic steatosis based on FLI; the magnitude of the associations remained reasonably stable, but it became weaker ($p > 0.05$) after excluding fruits, cereals, dairy products, red or processed meat, or alcohol.

In sensitivity analyses, when excluding the alcohol component from the MDS but adjusting for alcohol consumption as a covariate, the inverse associations between MDS and risk of hepatic steatosis based on FLI became weaker (**Table S4**). The primary results were not different when excluding participants with $\text{BMI} \geq 30 \text{ kg/m}^2$, excessive alcohol consumption, or secondary causes of hepatic steatosis (**Table S4**). Excluding participants with implausible energy intakes weakened the associations (**Table S4**). The analysis of an

1
2
3 224 alternative definition of prevalent hepatic steatosis, excluding participants with only high FLI
4
5 225 score at baseline, did not alter the significant inverse association between MDS and risk of
6
7 226 FLI-based hepatic steatosis (**Table S5**). Effect sizes were of slightly higher magnitude when
8
9 227 excluding those with $FLI > 30$ or $NAFLD\text{-}score \geq -0.640$ at baseline, but CIs were wider due to
10
11 228 smaller sample size (**Table S6**).

12
13
14
15 229 For NAFLD-score, no significant associations were found in any of the sensitivity
16
17 230 analyses (**Tables S4 and S5** and **Figure S2**). The sole exception was when participants with a
18
19 231 high NAFLD-score at baseline were excluded, where an inverse association between MDS
20
21 232 quintiles and risk of hepatic steatosis was present ($p_{trend}=0.039$), but this association was
22
23 233 attenuated to the null after adjustment for BMI (**Table S5**).

24
25
26
27
28 234 *Longitudinal analyses for adiposity and markers of hepatic function*
29

30
31 235 In post-hoc exploratory analyses there were inverse associations of MDS with changes
32
33 236 in BMI [β coefficient (95% CIs) per one SD higher MDS of -0.08 (-0.15, -0.02)] and in waist
34
35 237 circumference [-0.33 (-0.61, -0.06)] (**Table S7**). For the markers of hepatic function, MDS
36
37 238 showed a trend toward inverse association with GGT levels ($p_{trend}=0.047$) [β coefficient (95%
38
39 239 CIs) per one SD higher MDS of -1.66 (-3.73, 0.41)], but not with ALT or AST levels (**Table**
40
41 240 **S8**).

42
43
44
45
46 241 **DISCUSSION**
47

48
49 242 In this first population-based European study among adults free from clinically
50
51 243 manifest hepatic steatosis to report on the prospective association between adherence to the
52
53 244 Mediterranean diet and risk of hepatic steatosis, we found an inverse association between
54
55 245 MDS and risk of hepatic steatosis based on FLI criteria. This relationship was attenuated to
56
57 246 the null when controlled for general and central adiposity assessed by the BMI and waist
58
59
60

circumference. In contrast, there was no association between adherence to the Mediterranean diet and risk of hepatic steatosis based on NAFLD-score criteria.

Current findings in context of other evidence

Our finding based on FLI is consistent with the only published prospective study relating the Mediterranean diet to hepatic steatosis, where each SD increase in MDS was estimated to decrease the odds for incident hepatic steatosis by 26% (95% CI 10%-39%) [26]. By contrast, the point estimate of the effect size in our study was smaller [(16% (95% CI 4%-27%)). A possible explanation partly lies in methodological differences. We used biochemical and anthropometric markers to estimate hepatic steatosis in the current study, while the previous study used computed tomography assessment.

No association was found between adherence to the Mediterranean diet and risk of hepatic steatosis based on the NAFLD-score. For possible explanations based on the differences in their components, the FLI includes GGT, while NAFLD-score includes AST and AST/ALT ratio; the FLI includes adiposity markers, while the NAFLD-score does not; the FLI includes a lipid marker (triglycerides) while NAFLD-score includes markers of glycaemic status. Previous studies showed a modest association of GGT and ALT (but not AST) with the prevalence of hepatic steatosis [1]. Indeed, our analysis showed an inverse association between MDS and GGT levels, but not with AST or ALT, and these findings could explain the discrepancy between the two indices. Notably, our sensitivity analyses using different definitions of hepatic steatosis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on NAFLD-score after excluding participants with high baseline NAFLD-score only. This could be explained by modest concordance between the two measures. Of note, there were no statistically significant associations between MDS and risk of hepatic steatosis based on FLI after excluding participants with FLI>30 at

baseline, which led to a smaller sample size and consequently a lower statistical power in our study. The inverse association between MDS and risk of hepatic steatosis defined by FLI remained significant after adjusting for BMI only but became imprecise and not significant after adjusting for both BMI and waist circumference or for changes in BMI over the follow-up period. These results suggest the collinearity between the central adiposity and hepatic steatosis as the central adiposity may partly reflect hepatic steatosis. This biologically plausible finding is in agreement with previous cross-sectional findings for MDS and prevalent hepatic steatosis in CoLaus study and the British Fenland Study we reported [25] and a study in Hong Kong [38]. Our finding that the MDS was negatively associated with an increase in BMI after 5.3 years of follow-up is consistent with the findings from the Framingham Heart Study which observed the same trend over 6-year follow-up [26]; and from Nurses' Health Study and Health Professionals' Follow-up Study evaluating 20-year longitudinal data with repeated self-reported measures of diet and adiposity measures [39].

Sequential subtraction of different components of the MDS showed that fruits, cereals, dairy products, red or processed meat, or alcohol partially accounted for the observed association. These findings agree with previous studies [24,26,40,41] including the Framingham Heart Study suggesting benefits of low consumption of red meat and high consumption of fruits or whole grains [26]; and a cross-sectional analysis from the PREDIMED study suggesting the benefit of low consumption of red meat [24]. Moreover, the Mediterranean diet is characterized by a moderate-to-high consumption of whole grains, which has been inversely associated with the likelihood of having NAFLD [42].

Possible mechanisms and implications

Different components of the Mediterranean diet, mainly omega 3 polyunsaturated fatty acids (PUFA), fibre, and antioxidants, are inversely associated with hepatic steatosis [43,44].

High levels of polyphenols found in fruits and vegetables and high levels of monounsaturated fatty acids of olive oil have been shown to inhibit *de novo* lipogenesis, improve peripheral insulin sensitivity, and reduce cardiovascular risk mainly due to their antioxidant, anti-inflammatory, and anti-fibrotic effects [16,45]. One meta-analysis of interventional studies reported that omega-3 PUFA were negatively associated with hepatic steatosis [46]. The Mediterranean diet is also low in saturated fat, which has been demonstrated to increase hepatic triglycerides content and hepatic insulin resistance [47,48]. Finally, the high fibre content of the Mediterranean diet has been associated with reduced hepatic fat [16,43].

Hepatic steatosis is associated with cardiometabolic diseases and substantially impacts public health [11,13,14]. Thus, our finding of an inverse association between Mediterranean diet and risk of hepatic steatosis strongly reinforces the importance of dietary advice for the prevention of hepatic steatosis. However, future work should confirm whether or not the clinical importance of the Mediterranean diet for the prevention of hepatic steatosis is independent of obesity or central adiposity.

Strengths and limitations

To our knowledge, this is the first European prospective study assessing the association between the Mediterranean diet and risk of hepatic steatosis. The study had the benefit of a relatively large sample size and an average of 5.3 years of follow-up, and applied a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean population [31].

Several limitations of this study merit consideration. Measurement error and recall bias are inevitable when using self-reported dietary instruments, limiting the ability to precisely measure adherence to the Mediterranean diet, although adjustment for energy intake may have reduced the magnitude of measurement error [49]. Our ascertainment of hepatic

steatosis was based on two indices, but not on liver biopsy or direct imaging assessment; hence, information bias (misdiagnosis) cannot be ruled out. Although liver biopsy is the gold standard for diagnosing hepatic steatosis, its use in apparently healthy participants would be unethical and unfeasible in a large population-based study. Further, previous studies have shown that FLI and NAFLD-score can accurately identify hepatic steatosis with good sensitivity and specificity, and these scores have been validated for use in large epidemiological studies [34,35,50,51]. Although we adjusted for many relevant confounders and performed a series of sensitivity analyses, we cannot rule out residual confounding due to unmeasured variables or covariates measured with error. Generalisability is limited because included participants seemed to be healthier than those excluded, and our findings were obtained in a single European population. Still, they confirm the findings from a previous prospective study conducted in the US [26], and might serve as a reference for other studies.

Conclusion

Adherence to the Mediterranean diet was inversely associated with risk of hepatic steatosis based on the FLI, and the association was independent of several known risk factors. Conversely, the association was not observed when using different criteria specifying the NAFLD-score. These findings support recommendations on following the Mediterranean diet for hepatic steatosis prevention in addition to the existing evidence for its benefit for cardiovascular disease prevention. Nonetheless, the findings also highlight the need for further research with more accurate measures of hepatic steatosis to replicate these findings in different populations and settings.

345 DECLARATION

346 **Acknowledgements:** The authors are grateful to all the participants and staff of CoLaus study.

347 **Conflict of Interest:** None.

348 **Ethics approval and consent to participate:** The institutional Ethics Committee of the
349 University of Lausanne, which afterwards became the Ethics Commission of Canton Vaud
350 (www.cer-vd.ch) approved the baseline CoLaus study (reference 16/03); the approval was
351 renewed for the first (reference 33/09) and the second (reference 26/14) follow-ups.

352 The CoLaus study was performed in agreement with the Helsinki declaration and its
353 former amendments, and all participants provided their written informed consent before
354 entering the study.

Abbreviations: TEE, total energy expenditure; BMI, body mass index; iqr, interquartile range; GGT, gamma-glutamyl transferase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

* The population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score. P-values were computed by using ANOVA for continuous variables and Chi-square test for categorical variables.

† Alcohol consumption categorized as “abstainers” (0 unit/week), “moderate” (1–21 units/week for men, 1–14 for women), and “heavy drinkers” (>21 units/week for men, >14 for women).

‡ Metabolic syndrome defined according to the International Diabetic Federation (waist circumference ≥94 cm in men and ≥80 cm in women plus at least two of the following factors: serum triglycerides ≥1.70 mmol/L or specific treatment for this lipid abnormality; serum high-density lipoprotein cholesterol <1.03 mmol/L in men and <1.29 mmol/L in women or specific treatment for this lipid abnormality; systolic blood pressure ≥130 mm Hg or diastolic blood pressure ≥85 mm Hg or treatment for previously diagnosed hypertension; and fasting plasma glucose ≥5.6 mmol/L or previously diagnosed type 2 diabetes).

Abbreviations: iqr, interquartile range; BMI, body mass index; WC, waist circumference; NAFLD, non-alcoholic fatty liver disease.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

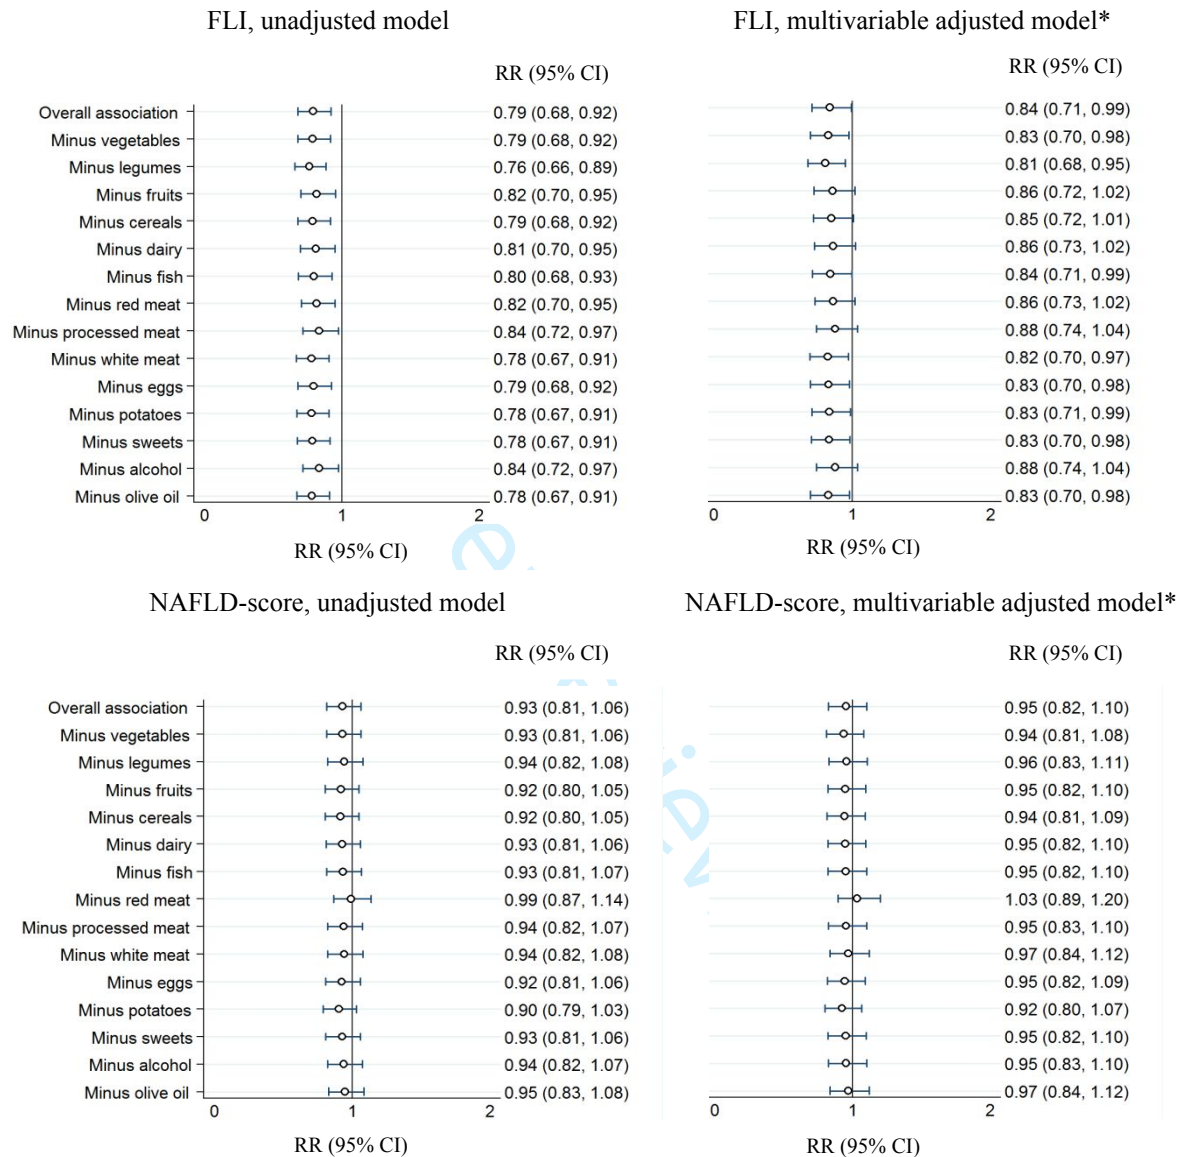

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

Figure 1 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2288): sensitivity analysis to examine influence of each component of Mediterranean diet.

Abbreviations: FLI, fatty liver index; NAFLD, non-alcoholic fatty liver disease.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

Risk ratio (RR) and 95% confidence intervals (CI) were estimated per one standard deviation of MDS (overall association) or of each MDS computed after excluding one component.

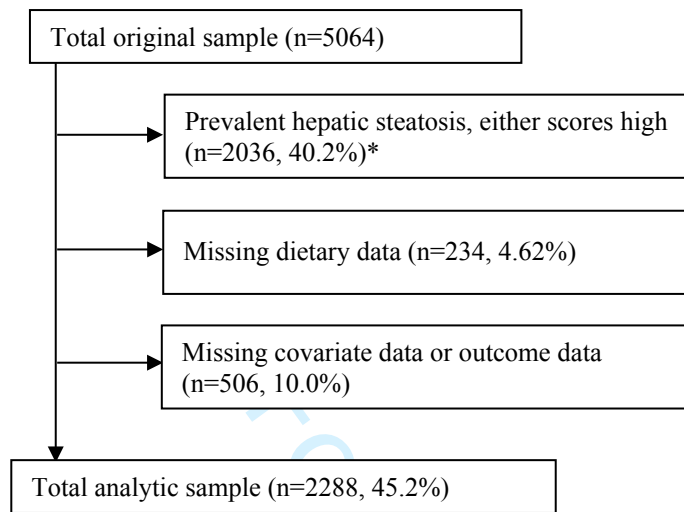

* Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and

Abbreviations: SES, socio-economic status; BMI, body mass index; MetS, metabolic syndrome; NAFLD, non-alcoholic fatty liver disease; SD, standard deviation; CI, confidence interval.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for different multivariable analyses.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Changes in BMI categories defined as individuals with a normal BMI at baseline and follow-up, individuals with normal BMI at baseline and overweight or obese BMI at follow-up, individuals with overweight or obese BMI at baseline and at follow-up, or individuals with overweight or obese BMI at baseline and normal at follow-up.

|| Results of further adjustment for waist circumference were broadly in line with of the further adjustment for BMI (data not shown).

**Family history of diabetes (yes/no), high blood pressure (yes/no), high triglyceride level (yes/no), low HDL level (yes/no), and high glucose level (yes/no).

†† Metabolic syndrome as defined by the International Diabetes Federation (yes/no).

‡‡ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

Abbreviations: SES, socio economic status; BMI, body mass index; MD, Mediterranean Diet; NAFLD, non-alcoholic fatty liver disease; SD, standard deviation; CI, confidence interval.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.41 after excluding alcohol from Mediterranean Diet score components, 1.20 after excluding participants with BMI≥30, 1.18 after excluding participants with excessive alcohol consumption, 1.20 after excluding participants with probable implausible energy intake or after excluding participants with secondary causes of hepatic steatosis or diabetes.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Results of further adjustment for waist circumference were broadly in line with of the further adjustment for BMI (data not shown).

l Excluded 36 participants with BMI≥30 kg/m².

** Excessive alcohol consumption defined as >21 units per week for men and >14 units per weeks for women; excluded 60 participants with excess alcohol consumption (n=2228).

†† Implausible energy intake defined as <500 and <800 kcal or >3,500 or >4,000 kcal in women and men, respectively; excluded 4 participants with probable implausible energy intake (n=2247).

‡‡ Secondary causes of hepatic steatosis defined as having hepatitis B, C or HIV, and with hepatotoxic medications (Glucocorticoids, isoniazid, methotrexate, amiodarone, and tamoxifen); excluded 36 participants with probable secondary causes of hepatic steatosis (n=2252).
§§ Diabetes defined as glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of hypoglycaemic drugs or insulin; excluded 26 participants with probable secondary causes of hepatic steatosis (n=2262).
¶¶ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

STROBE 2007 (v4) Statement—Checklist of items that should be included in reports of cohort studies

Section/Topic	Item #	Recommendation	Reported on page #
Title and abstract	1	(a) Indicate the study’s design with a commonly used term in the title or the abstract	3
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	3
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	6
Objectives	3	State specific objectives, including any prespecified hypotheses	7
Methods			
Study design	4	Present key elements of study design early in the paper	7
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	7
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up	7; Figure S1, and table S1
		(b) For matched studies, give matching criteria and number of exposed and unexposed	N/A
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	Pages 7 to 10
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	Pages 7 to 10
Bias	9	Describe any efforts to address potential sources of bias	Pages 10 & 11
Study size	10	Explain how the study size was arrived at	12; Figure S1
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	Pages 7 to 10
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	Pages 10 & 11
		(b) Describe any methods used to examine subgroups and interactions	Pages 10 & 11
		(c) Explain how missing data were addressed	Pages 10 & 11
		(d) If applicable, explain how loss to follow-up was addressed	Pages 10 & 11
		(e) Describe any sensitivity analyses	Pages 10 & 11

Results				
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed		12
		(b) Give reasons for non-participation at each stage		N/A
		(c) Consider use of a flow diagram		Figure 1
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders		12; Table 1 and table S1 & S2
		(b) Indicate number of participants with missing data for each variable of interest		12
		(c) Summarise follow-up time (eg, average and total amount)		12
Outcome data	15*	Report numbers of outcome events or summary measures over time		12; Table S2
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(b) Report category boundaries when continuous variables were categorized		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period		
Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses		Pages 13 & 14; Supplementary Tables S3 to S8
Discussion				
Key results	18	Summarise key results with reference to study objectives		14
Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision.		pages 17 & 18
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence		Pages 14 to 18
Generalisability	21	Discuss the generalisability (external validity) of the study results		pages 17 & 18
Other information				
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on		2

	which the present article is based	
--	------------------------------------	--

*Give information separately for cases and controls in case-control studies and, if applicable, for exposed and unexposed groups in cohort and cross-sectional studies.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). ABSTRACT

Objective: The Mediterranean diet has been promoted as a healthy dietary pattern but, whether the Mediterranean diet may help to prevent hepatic steatosis is not clear. This study aimed to evaluate the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis.

Design: Population-based prospective cohort study.

Setting: The Swiss CoLaus study.

Participants: We evaluated 2288 adults (65.4% women, aged 55.8±10.0 years) without hepatic steatosis at first follow-up in 2009-2012. Adherence to the Mediterranean diet was scaled as the Mediterranean diet score (MDS) based on the Mediterranean-diet Pyramid ascertained with responses to food-frequency questionnaires.

Outcome measures: New onset of hepatic steatosis was ascertained by two indices separately: the fatty liver index (FLI, ≥60 points) and the non-alcoholic fatty liver disease (NAFLD) score (≥-0.640 points). Prospective associations between adherence to the Mediterranean diet and risk of hepatic steatosis were quantified using Poisson regression.

Results: During a mean 5.3-years of follow-up, hepatic steatosis was ascertained in 153 (6.7%) participants by FLI criteria and in 208 (9.1%) by NAFLD-score. After multivariable adjustment, higher adherence to MDS was associated with lower risk of hepatic steatosis based on FLI: risk ratio (95% confidence interval) 0.84 (0.73, 0.96) per one standard deviation of MDS; 0.85 (0.73, 0.99) adjusted for BMI; and 0.85 (0.71, 1.02) adjusted for both BMI and waist circumference. When using NAFLD-score, no significant association was found between MDS and risk of hepatic steatosis [0.95 (0.83, 1.09)].

Conclusion: A potential role of the Mediterranean diet in the prevention of hepatic steatosis is suggested by the inverse association observed between adherence to the Mediterranean diet and incidence of hepatic steatosis based on the FLI. The inconsistency of this association

STRENGTHS AND LIMITATION OF THE STUDY

- This study had the benefit of a relatively large sample size and an average of 5.3 years of follow-up.
- We applied a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean population.
- Our ascertainment of hepatic steatosis was based on two indices that has been validated for use in large epidemiological studies.
- The precision of the two hepatic steatosis indices used is different and may be influenced by the presence of steatohepatitis or advanced liver fibrosis.
- Generalisability is limited because our findings relate to a single European population.

INTRODUCTION

Hepatic steatosis is the most common cause of liver disease [1]. In westernized countries, hepatic steatosis affects up to 34% of the general population and up to 74% of obese individuals, depending on the definition used [2–4]. Hepatic steatosis—fat content of more than 5% of liver volume—is the first recognizable stage of non-alcoholic fatty liver disease (NAFLD) [1]. Hepatic steatosis, particularly NAFLD, may progress to end-stage liver disease including fibrosis, cirrhosis, and hepatocellular carcinoma [5]. Moreover, as hepatic steatosis increases the risk of metabolic syndrome, type 2 diabetes, and cardiovascular disease (CVD), its prevention is of public health importance [6]. An unhealthy dietary pattern remains one of the primary targets of lifestyle modification for the prevention and management of hepatic steatosis and NAFLD [7,8].

The Mediterranean diet has been recently recommended for treatment of NAFLD [9]. In recent years, a growing body of evidence supports the idea that the Mediterranean diet may be the reference nutritional profile for the prevention of hepatic steatosis development [10–12]. Adherence to the Mediterranean diet has been reported to have a beneficial impact on risks of CVD [13,14], type 2 diabetes [15], and metabolic syndrome [16]. Trial evidence demonstrated the potential benefits of the Mediterranean diet against progress of hepatic steatosis focusing on individuals with existing hepatic steatosis, either alone [17–22] or associated with metabolic risk factors such as obesity or diabetes [22–25]. Research among those without clinically manifest hepatic steatosis is restricted to observational evidence, reporting an inverse association that greater adherence to a Mediterranean diet is associated with lower prevalence of hepatic steatosis [26,27]. However, the cross-sectional design of these studies limits inference for causal associations and can be used mainly for hypothesis generation. Relevant longitudinal evidence for the primary prevention of hepatic steatosis or NAFLD has been reported only by the Framingham Heart Study, with a significant inverse

association of adherence to the Mediterranean diet with risk of hepatic steatosis in 1521 adults over 6 years of follow-up [28], but evidence is lacking in Europe.

Given the limited evidence from population-based epidemiological studies thus far, we aimed to investigate the prospective association between adherence to the Mediterranean diet and the risk of developing hepatic steatosis among adults without clinically manifest hepatic steatosis. We hypothesized that greater adherence to the Mediterranean diet would reduce the risk of hepatic steatosis.

METHODS

Study population

We evaluated participants in the CoLaus study, an ongoing population-based cohort investigating the clinical, biological, and genetic determinants of CVD in the city of Lausanne, Switzerland [29]. Inclusion criteria of the recruitment were adults of European origin, aged 35 to 75 years [29]. There were three study phases: baseline recruitment in 2003-2006 (n=6733), the first follow-up in 2009-2012 (n=5064), and the second follow-up in 2014-2017 (n=4881). We conducted dietary assessment at the first follow-up and therefore considered the first follow-up as the study baseline. Fatty liver index (FLI) and NAFLD-score, two indices of hepatic steatosis, were available at baseline [27]. If participants met the joint criterion of $FLI \geq 60$ or $NAFLD\text{-score} \geq -0.640$ at baseline, we excluded them as prevalent cases (see below) (n=2036). We also excluded participants with missing information on diet, outcome, and covariates (n=740) (**Figure S1**).

Patient and public involvement

Patients and/or the public were not involved in the design, conduct, reporting or dissemination plans of this research.

71 *Dietary assessment*

72 Participants completed a self-administered, 97-item, semi-quantitative food frequency
73 questionnaire (FFQ) about their habitual dietary intake over the last four weeks [30], the
74 validity of which had been assessed in canton Geneva against 24-hour recalls [30,31]. For
75 each item, participants were instructed to report consumption frequencies by selecting one of
76 the seven frequency options from “less than once during the last 4 weeks” to “2 or more times
77 per day” and by selecting a usual serving size (smaller, equal, or bigger to a reference size).

78 *Mediterranean diet scores*

79 We derived the pyramid-based Mediterranean diet score (MDS) as a measure of
80 adherence to the Mediterranean diet from responses to the FFQ as we conducted previously
81 [27]. This MDS is based on the Mediterranean Dietary Pyramid proposed by the
82 Mediterranean Diet Foundation for both Mediterranean and non-Mediterranean countries and
83 accounting for the traditional Mediterranean diet, contemporary lifestyle, and food
84 environment [32]. We have previously reported that this MDS scoring algorithm predicted
85 CVD incidence [33], as well as the prevalence of hepatic steatosis [27] in non-Mediterranean
86 populations. Briefly, a continuous score of 0 to 1 was assigned for each recommended level of
87 the 15 components of the pyramid (vegetables, legumes, and fish as healthy items; red meat,
88 processed meat, potato, and sweets as unhealthy items; and fruits, nuts, cereals, eggs, dairy,
89 white meat, and alcoholic beverages as items for which moderate consumption was
90 recommended). The resulting MDS ranges between 0 and 15 on a continuous scale. The MDS
91 calculation was adjusted to an energy intake of 2000 kcal/d (8.37 MJ/day) by applying a
92 regression-residual technique for energy adjustment to each food group variable [33,34].

93 *Ascertainment of hepatic steatosis*

Two indices of hepatic steatosis were evaluated: fatty liver index (FLI) [35] and NAFLD liver fat score [36]. FLI was calculated based on a logistic function including body-mass index (BMI), waist circumference, fasting triglycerides, and gamma-glutamyl transferase (GGT) levels as follows:

$$FLI = 1 / (1 + e^{-(0.953 \times \ln(\text{triglycerides}) + 0.139 \times \text{BMI} + 0.718 \times \ln(\text{GGT}) + 0.053 \times \text{waist circumference} - 15.745)})$$

FLI×100 ranges from 0 to 100. Presence of hepatic steatosis was defined by $FLI \geq 60$, a value with a sensitivity of 61% and a specificity of 86% [35]. FLI was tested previously in comparison to ultrasonography with an area under the receiver operating characteristic curve of 0.78 (OR 95% CI: 0.77, 0.83) [37].

The NAFLD-score was calculated based on an algorithm including a logistic function with the presence of metabolic syndrome defined by criteria of International Diabetes Federation [38], presence of type 2 diabetes, and fasting concentrations of insulin, aspartate-aminotransferase (AST), and the AST/ alanine transaminase (ALT) ratio:

$$\begin{aligned} \text{NAFLD-score} = & -2.89 + 1.18 \times \text{metabolic syndrome (yes/no)} + 0.45 \times \text{type 2 diabetes (yes /no)} + 0.15 \\ & \times \text{fasting-insulin (mU/L)} + 0.04 \times \text{fasting-AST (U/L)} - 0.94 \times \text{AST/ALT} \end{aligned}$$

Presence of hepatic steatosis was defined by a NAFLD-score ≥ -0.640 , a value with a sensitivity of 86% and a specificity of 71%, when compared to proton magnetic resonance imaging [36].

Assessment of covariates at baseline

Sociodemographic, lifestyle and health characteristics were collected by self-administered questionnaires. Age, sex, marital status, occupational status, and educational level were included as indicators of sociodemographic condition. Smoking status was classified as ‘never’, ‘former’, and ‘current’. Alcohol consumption was assessed by the

1
2
3 117 number of alcoholic beverage units consumed in the past week and further categorized as
4
5 118 ‘abstainers’ (0 unit/week), ‘moderate’ (1–21 units/week for men, 1–14 for women), and
6
7 119 ‘heavy’ (>21 units/week for men, >14 for women) drinkers (one unit corresponds to 8 g of
8
9
10 120 alcohol). Physical activity was assessed with a self-administered quantitative physical activity
11
12 121 frequency questionnaire [39]. Health characteristics included presence of metabolic syndrome
13
14 122 and family history of diabetes. Anthropometric and blood pressure measurements were
15
16 123 obtained using standard procedures and equipment as previously described [29]. Plasma
17
18 124 triglycerides, high-density lipoprotein cholesterol, and glucose were measured using standard
19
20 125 enzymatic methods and ALT, AST, and GGT were measured using reference methods as
21
22 126 standardized by the International Federation of Clinical Chemistry.
23
24
25
26

27 127 *Statistical analysis*
28
29

30 128 Statistical analyses were performed using Stata (version 15; StataCorp, College
31
32 129 Station, TX, USA) with a two-sided test with $\alpha=0.05$. Descriptive statistics were obtained in
33
34 130 the participants included in this study in comparison to those excluded from this study.
35
36 131 Cohen’s kappa statistics were calculated to assess the agreement between the FLI and
37
38 132 NAFLD-score.
39
40
41
42

43 133 MDS as a measure of adherence to the Mediterranean diet was evaluated both
44
45 134 categorically (quintiles) and continuously scaled as one SD unit. The association of MDS with
46
47 135 the risk of hepatic steatosis was assessed using multivariable-adjusted Poisson regression
48
49 136 models with robust standard errors and estimating risk ratios (RRs) and 95% confidence
50
51 137 intervals (CIs). Models were adjusted for age, sex, marital status, occupational status,
52
53 138 educational level, smoking status, energy intake, total energy expenditure, and date of dietary
54
55 139 assessment (to adjust for seasonality). We further adjusted for BMI and waist circumference
56
57 140 as potential confounders or factors on the causal pathway to assess the possible impact of
58
59
60

141 overall and central adiposity on the association of the Mediterranean diet and hepatic
142 steatosis.

143 Additionally, we also adjusted for changes in BMI categories between baseline and
144 follow-up; for alcohol consumption (units/week); for clinical variables of metabolic risk
145 [blood pressure >130/85 mm Hg (yes/no), triglycerides >1.7 mmol/L (yes/no), high-density
146 lipoprotein level <1.29 mmol/L for men and <1.03 mmol/L for women (yes/no), and glucose
147 level ≥ 5.6 mmol/L (yes/no)] [38]; and for family history of diabetes and metabolic syndrome
148 (only for FLI) to examine their influence on the association of interest.

149 Possible interactions between MDS and age, sex, BMI, and alcohol consumption were
150 tested using the Wald test. Several sensitivity analyses were conducted to examine the
151 robustness of the observed findings. First, to assess the role of alcohol consumption (as
152 alcohol is a risk factor for fatty liver accumulation), we excluded the alcohol component from
153 the MDS, while adjusting for alcohol consumption as a covariate. We took the same
154 approaches for the other MDS components to assess the impact of each component on the
155 observed associations. Second, we conducted separate analyses after excluding participants
156 with BMI ≥ 30 kg/m²; implausible energy intake (<500 or >3500 kcal/day in women and <800
157 or >4000 kcal/day in men); excessive alcohol consumption; prevalent diabetes (defined as
158 glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of
159 hypoglycaemic drugs or insulin); or probable secondary causes of hepatic steatosis such as
160 hepatitis B or C, HIV, hepatotoxic, or autoimmune disease medications. We evaluated the
161 robustness of the results to an alternative definition of prevalent hepatic steatosis. While we
162 excluded participants with prevalent hepatic steatosis using the specified cut-offs of FLI or
163 NAFLD-score in the primary analysis, we used each of the two indices separately in
164 sensitivity analyses, whereby we evaluated 2652 adults in longitudinal analysis based on FLI;

60

and 2568 adults, based on NAFLD. Finally, we used more restrictive cutpoints and excluded participants with NAFLD-score ≥ -0.640 or with $FLI > 30$.

In a post-hoc analysis, due to inconsistency of the associations observed for FLI and NAFLD-score, we also calculated the hepatic steatosis index (HSI) [40] based on the ratio of AST/ALT , BMI , presence of type 2 diabetes, and sex:

$$HSI = 8 * AST/ALT + BMI + 2 \text{ (presence of diabetes)} + 2 \text{ (if women)}$$

Presence of hepatic steatosis was defined by a $HSI > 36$. After excluding participants with $HSI > 36$ at baseline ($n = 2674$), we evaluated 2351 adults.

In a post-hoc analysis pertaining to sensitivity of the results to model covariates and for better understanding of potential mechanisms, longitudinal associations of MDS with follow-up measures of log-transformed GGT , ALT , and AST levels and with changes in BMI and waist circumference from baseline to follow-up were examined using multivariable-adjusted linear regression. These results were expressed as β coefficient (95% CIs) for changes in each measure per 1-SD difference in MDS .

RESULTS

Participant characteristics

Of the initial 5064 participants, 2776 (54.8%) were excluded, leaving 2288 participants (65.4% women; 55.8 ± 10.0 years) for analysis. Participants included were more likely to be women, show higher sociodemographic characteristics and lower BMI , waist circumference, liver enzymes, or prevalence of metabolic syndrome in comparison to excluded individuals (**Table S1**). Being in the highest quintile of MDS was higher among women compared to men, positively correlated with sociodemographic characteristics, and

negatively correlated with being current smokers, heavy alcohol drinkers, and with BMI, waist circumference, GGT, and TG (**Table 1**).

Adherence to the Mediterranean diet and risk of hepatic steatosis

After a mean 5.3 (SD: 0.5) years of follow-up, there were 153 (6.7%) and 208 (9.1%) participants with hepatic steatosis based on FLI and NAFLD-score, respectively (**Table S2**). Case identification by FLI and NAFLD-score was modestly concordant ($\kappa=0.60$).

Multivariable-adjusted analysis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on FLI ($p_{\text{trend}} < 0.006$) with RR (95% CI) comparing the top to the bottom category of 0.50 (0.28, 0.91). The inverse associations across quintiles of MDS weakened after adjustment for BMI ($p_{\text{trend}} = 0.031$) or both BMI and waist circumference ($p_{\text{trend}} = 0.034$) (**Table 2**): RR (95% CI) = 0.61 (0.34, 1.09) and 0.60 (0.34, 1.08), respectively. In analyses using MDS as a continuous variable, the inverse association with risk of hepatic steatosis based on FLI [RR 0.84 (0.73, 0.96) per one SD of MDS] remained unchanged but getting imprecise after adjustment for BMI [RR 0.85 (0.73, 0.99)] and adjustment for both BMI and waist circumference [0.85 (0.71, 1.02)]. In sensitivity analysis, the magnitude of the inverse associations little changed after further adjustment for alcohol consumption, presence of metabolic syndrome, changes in BMI categories or clinical variables (medication use or prevalent diseases), while adjustment for BMI and clinical variables increased standard errors (**Table S3**).

Conversely, there was no association between MDS and the risk of hepatic steatosis defined by NAFLD-score criteria, with RRs (95% CIs) ranging from 0.93 (0.82, 1.05) to 1.00 (0.86, 1.17) over different regression models (**Table 2** and **Table S3**).

No significant interactions were found between MDS and age, sex, BMI, or alcohol consumption on risk of hepatic steatosis ($p_{\text{interaction}} > 0.05$; results not shown). The contribution of each component of the MDS on risk of hepatic steatosis was assessed by sequential subtraction of components from the score (**Figure 1**). Excluding the components of the MDS did not substantially affect the inverse associations with hepatic steatosis based on FLI; the magnitude of the associations remained reasonably stable, but it became weaker ($p > 0.05$) after excluding fruits, cereals, dairy products, red or processed meat, or alcohol.

In sensitivity analyses, when excluding the alcohol component from the MDS but adjusting for alcohol consumption as a covariate, the inverse associations between MDS and risk of hepatic steatosis based on FLI became weaker (**Table S4**). The primary results were not different when excluding participants with $\text{BMI} \geq 30 \text{ kg/m}^2$, excessive alcohol consumption, or secondary causes of hepatic steatosis (**Table S4**). Excluding participants with implausible energy intakes weakened the associations (**Table S4**). The analysis of an alternative definition of prevalent hepatic steatosis, excluding participants with only high FLI score at baseline, did not alter the significant inverse association between MDS and risk of FLI-based hepatic steatosis (**Table S5**). In post-hoc analyses, there was an inverse association between MDS quintiles and risk of hepatic steatosis based on HSI ($p_{\text{trend}} = 0.070$) with RR (95% CI) comparing the top to the bottom category of 0.70 (0.55, 0.91); a significant inverse association with HSI was observed per one SD increase in MDS [RR 0.90 (0.82, 0.98)] (**Table S5**). Effect sizes were of slightly higher magnitude when excluding those with $\text{FLI} > 30$ or $\text{NAFLD-score} \geq -0.640$ at baseline, but CIs were wider due to smaller sample size (**Table S6**).

For NAFLD-score, no significant associations were found in any of the sensitivity analyses (**Tables S4 and S5 and Figure S2**). The sole exception was when participants with a high NAFLD-score at baseline were excluded, where an inverse association between MDS

quintiles and risk of hepatic steatosis was present ($p_{\text{trend}}=0.039$), but this association was attenuated to the null after adjustment for BMI (Table S5).

Longitudinal analyses for adiposity and markers of hepatic function

In post-hoc exploratory analyses there were inverse associations of MDS with changes in BMI [β coefficient (95% CIs) per one SD higher MDS of -0.08 (-0.15, -0.02)] and in waist circumference [-0.33 (-0.61, -0.06)] (Table S7). For the markers of hepatic function, MDS showed a trend toward inverse association with GGT levels ($p_{\text{trend}}=0.047$) [β coefficient (95% CIs) per one SD higher MDS of -1.66 (-3.73, 0.41)], but not with ALT or AST levels (Table S8).

DISCUSSION

In this first population-based European study among adults free from clinically manifest hepatic steatosis to report on the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis, we found an inverse association between MDS and risk of hepatic steatosis based on FLI criteria. This relationship was attenuated to the null when controlled for general and central adiposity assessed by the BMI and waist circumference. In contrast, there was no association between adherence to the Mediterranean diet and risk of hepatic steatosis based on NAFLD-score criteria.

Current findings in context of other evidence

Our finding based on FLI is consistent with the only published prospective study relating the Mediterranean diet to hepatic steatosis, where each SD increase in MDS was estimated to decrease the odds for incident hepatic steatosis by 26% (95% CI 10%-39%) [28]. By contrast, the point estimate of the effect size in our study was smaller [(16% (95% CI 4%-27%)). A possible explanation partly lies in methodological differences. We used biochemical

and anthropometric markers to estimate hepatic steatosis in the current study, while the previous study used computed tomography assessment.

No association was found between adherence to the Mediterranean diet and risk of hepatic steatosis based on the NAFLD-score. For possible explanations based on the differences in their components, the FLI includes GGT, while NAFLD-score includes AST and AST/ALT ratio; the FLI includes adiposity markers, while the NAFLD-score does not; the FLI includes a lipid marker (triglycerides) while NAFLD-score includes markers of glycaemic status. Previous studies showed a modest association of GGT and ALT (but not AST) with the prevalence of hepatic steatosis [1]. Indeed, our analysis showed an inverse association between MDS and GGT levels, but not with AST or ALT, and these findings could explain the discrepancy between the two indices. Notably, our sensitivity analyses using different definitions of hepatic steatosis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on NAFLD-score after excluding participants with high baseline NAFLD-score only. This could be explained by modest concordance between the two measures. Of note, there were no statistically significant associations between MDS and risk of hepatic steatosis based on FLI after excluding participants with FLI>30 at baseline, which led to a smaller sample size and consequently a lower statistical power in our study. In a post-hoc analysis, we found an inverse association between adherence to the Mediterranean diet and hepatic steatosis as assessed by HSI, an alternative score to detect hepatic steatosis. Although, case identification by HSI and FLI (kappa=0.27) or NAFLD-score (Kappa=0.18) was weakly concordant; our finding based on FLI is consistent with HSI. This could be explained potentially by BMI as one of the components of both FLI and HSI, highlighting the importance of obesity for incident hepatic steatosis [41].

The inverse association between MDS and risk of hepatic steatosis defined by FLI remained significant after adjusting for BMI only but became imprecise and not significant

after adjusting for both BMI and waist circumference or for changes in BMI over the follow-up period. These results suggest the collinearity between the central adiposity and hepatic steatosis as the central adiposity may partly reflect hepatic steatosis. This biologically plausible finding is in agreement with previous cross-sectional findings for MDS and prevalent hepatic steatosis in CoLaus study and the British Fenland Study we reported [27] and a study in Hong Kong [42]. Our finding that the MDS was negatively associated with an increase in BMI after 5.3 years of follow-up is consistent with the findings from the Framingham Heart Study which observed the same trend over 6-year follow-up [28]; and from Nurses' Health Study and Health Professionals' Follow-up Study evaluating 20-year longitudinal data with repeated self-reported measures of diet and adiposity measures [43].

Sequential subtraction of different components of the MDS showed that fruits, cereals, dairy products, red or processed meat, or alcohol partially accounted for the observed association. These findings agree with previous studies [26,28,44,45] including the Framingham Heart Study suggesting benefits of low consumption of red meat and high consumption of fruits or whole grains [28]; and a cross-sectional analysis from the PREDIMED study suggesting the benefit of low consumption of red meat [26]. Moreover, the Mediterranean diet is characterized by a moderate-to-high consumption of whole grains, which has been inversely associated with the likelihood of having NAFLD [46].

Possible mechanisms and implications

Hepatic steatosis is associated with a number of metabolic risk factors including insulin resistance, type 2 diabetes, dyslipidaemia, metabolic syndrome, and oxidative stress [47]. Mediterranean-diet associated phenolic compounds (phenolic acids and polyphenols) found in fruits and vegetables and high levels of monounsaturated fatty acids of olive oil have been shown to inhibit *de novo* lipogenesis, improve peripheral insulin sensitivity, and reduce

1
2
3 307 cardiovascular risk mainly due to their antioxidant, anti-inflammatory, and anti-fibrotic
4
5 308 effects [18,48–51]. Moreover, different components of the Mediterranean diet, including
6
7 309 omega 3 polyunsaturated fatty acids (PUFA), fibre, and antioxidant rich-foods, are inversely
8
9
10 310 associated with hepatic steatosis [52,53]. One meta-analysis of interventional studies reported
11
12 311 that omega-3 PUFA were negatively associated with hepatic steatosis [54]. The
13
14 312 Mediterranean diet is also low in saturated fat, which has been demonstrated to increase
15
16 313 hepatic triglycerides content and hepatic insulin resistance [55,56]. Finally, the high fibre
17
18 314 content of the Mediterranean diet has been associated with reduced hepatic fat [18,52].
19
20
21

22 315 Hepatic steatosis is associated with cardiometabolic diseases and substantially impacts
23
24 316 public health [13,15,16]. Thus, our finding of an inverse association between adherence to the
25
26 317 Mediterranean diet and risk of hepatic steatosis would support the importance of dietary
27
28 318 advice for the prevention of hepatic steatosis as well as its treatment. However, future work
29
30 319 should confirm whether or not the clinical importance of the Mediterranean diet for the
31
32 320 prevention of hepatic steatosis is independent of obesity or central adiposity.
33
34
35

36
37 321 *Strengths and limitations*
38
39

40 322 To our knowledge, this is the first European prospective study assessing the
41
42 323 association between the Mediterranean diet and risk of hepatic steatosis. The study had the
43
44 324 benefit of a relatively large sample size and an average of 5.3 years of follow-up, and applied
45
46 325 a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean
47
48 326 population [33].
49
50
51

52
53 327 Several limitations of this study merit consideration. Measurement error and recall
54
55 328 bias are inevitable when using self-reported dietary instruments, limiting the ability to
56
57 329 precisely measure adherence to the Mediterranean diet, although adjustment for energy intake
58
59 330 may have reduced the magnitude of measurement error [57]. We used diet data measured only
60

at baseline, and intra-individual variation over time might be present. However, we previously reported that dietary intake is stable in CoLaus study and in Switzerland in general [58,59].

Our ascertainment of hepatic steatosis was based on two indices, but not on liver biopsy or direct imaging assessment; hence, information bias (misdiagnosis) cannot be ruled out. Although liver biopsy is the gold standard for diagnosing hepatic steatosis, its use in apparently healthy participants would be unethical and unfeasible in a large population-based study. Further, previous studies have shown that FLI and NAFLD-score can accurately identify hepatic steatosis with good sensitivity and specificity, and these scores have been validated for use in large epidemiological studies [36,37,60,61]. But, although both FLI and NAFLD-score can indicate hepatic steatosis, their precision is variable [62]. Moreover, presence of steatohepatitis or advanced liver fibrosis could influence the relationship of FLI or NAFLD-score with hepatic steatosis [63]. Of note, our study was not designed to assess the role of adherence to the Mediterranean diet in hepatic fibrosis.

Although we adjusted for many relevant confounders and performed a series of sensitivity analyses, we cannot rule out residual confounding due to unmeasured variables or covariates measured with error. Generalisability is limited because included participants seemed to be healthier than those excluded, and our findings were obtained in a single European population. Still, they confirm the findings from a previous prospective study conducted in the US [28], and might serve as a reference for other studies.

Conclusion

Adherence to the Mediterranean diet was inversely associated with risk of hepatic steatosis based on the FLI, and the association was independent of several known risk factors. Conversely, the association was not observed when using different criteria specifying the NAFLD-score. These findings support recommendations on following the Mediterranean diet

355 for hepatic steatosis prevention in addition to the existing evidence for its benefit for
356 cardiovascular disease prevention. Nonetheless, the findings also highlight the need for
357 further research with more accurate measures of hepatic steatosis to replicate these findings in
358 different populations and settings.

Abbreviations: TEE, total energy expenditure; BMI, body mass index; iqr, interquartile range; GGT, gamma-glutamyl transferase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

* The population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score. P-values were computed by using ANOVA for continuous variables and Chi-square test for categorical variables.

† Alcohol consumption categorized as “abstainers” (0 unit/week), “moderate” (1–21 units/week for men, 1–14 for women), and “heavy drinkers” (>21 units/week for men, >14 for women).

‡ Metabolic syndrome defined according to the International Diabetic Federation (waist circumference ≥94 cm in men and ≥80 cm in women plus at least two of the following factors: serum triglycerides ≥1.70 mmol/L or specific treatment for this lipid abnormality; serum high-density lipoprotein cholesterol <1.03 mmol/L in men and <1.29 mmol/L in women or specific treatment for this lipid abnormality; systolic blood pressure ≥130 mm Hg or diastolic blood pressure ≥85 mm Hg or treatment for previously diagnosed hypertension; and fasting plasma glucose ≥5.6 mmol/L or previously diagnosed type 2 diabetes).

Table 2 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2,888).

	Risk ratio (95% CI) across quintiles of Mediterranean diet score*					<i>P</i> -trend	Risk ratio (95% CI) Per SD increase*

Abbreviations: iqr, interquartile range; BMI, body mass index; WC, waist circumference; NAFLD, non-alcoholic fatty liver disease.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

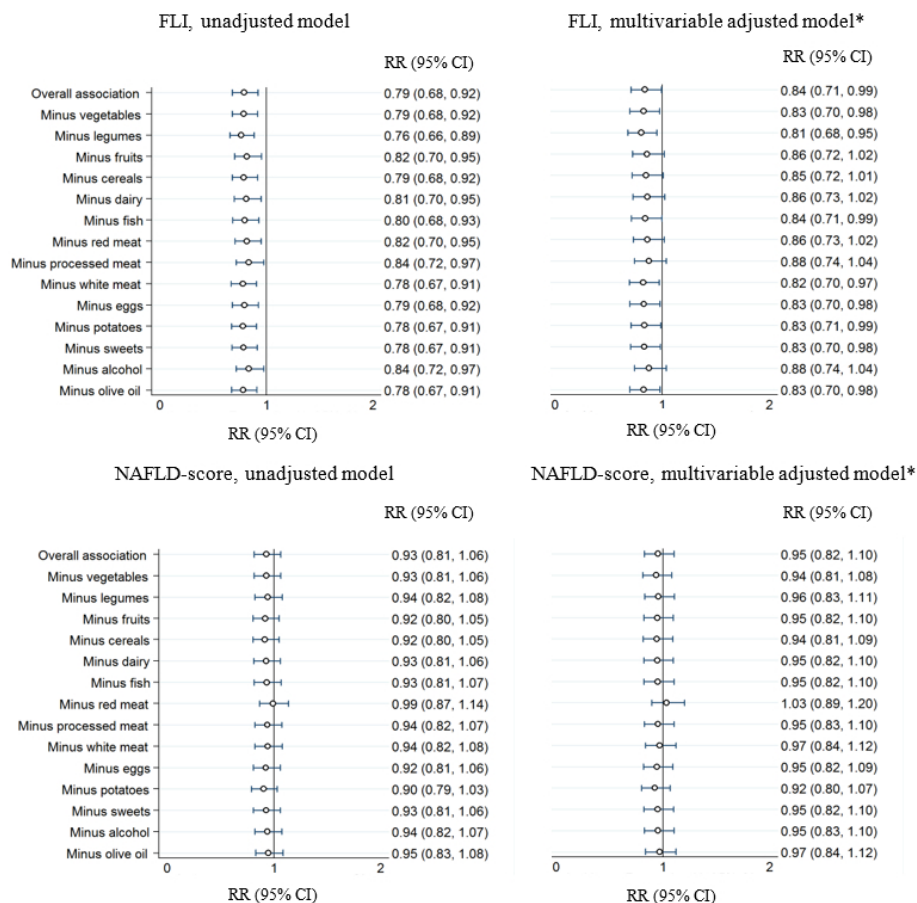

Figure 1 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2288): sensitivity analysis to examine influence of each component of Mediterranean diet.

Abbreviations: FLI, fatty liver index; NAFLD, non-alcoholic fatty liver disease.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

Risk ratio (RR) and 95% confidence intervals (CI) were estimated per one standard deviation of MDS (overall association) or of each MDS computed after excluding one component.

* Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

Abbreviations: SES, socio economic status; BMI, body mass index; MD, Mediterranean Diet; NAFLD, non-alcoholic fatty liver disease; SD, standard deviation; CI, confidence interval.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.41 after excluding alcohol from Mediterranean Diet score components, 1.20 after excluding participants with BMI≥30, 1.18 after excluding participants with excessive alcohol consumption, 1.20 after excluding participants with probable implausible energy intake or after excluding participants with secondary causes of hepatic steatosis or diabetes.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Results of further adjustment for waist circumference were broadly in line with of the further adjustment for BMI (data not shown).

‖ Excluded 36 participants with BMI≥30 kg/m².

** Excessive alcohol consumption defined as >21 units per week for men and >14 units per weeks for women; excluded 60 participants with excess alcohol consumption (n=2228).

†† Implausible energy intake defined as <500 and <800 kcal or >3,500 or >4,000 kcal in women and men, respectively; excluded 4 participants with probable implausible energy intake (n=2247).

‡‡ Secondary causes of hepatic steatosis defined as having hepatitis B, C or HIV, and with hepatotoxic medications (Glucocorticoids, isoniazid, methotrexate, amiodarone, and tamoxifen); excluded 36 participants with probable secondary causes of hepatic steatosis (n=2252).

§§ Diabetes defined as glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of hypoglycaemic drugs or insulin; excluded 26 participants with probable secondary causes of hepatic steatosis (n=2262).

¶¶ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

For peer review only

Abbreviations: iqr, interquartile range; GGT, gamma-glutamyl transferase; SES, socio economic status; BMI, body mass index; WC, waist circumference; ALT, Alanine transaminase; AST, aspartate-aminotransferase.

Statistical analysis using linear regression; results are expressed as β coefficients and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

STROBE 2007 (v4) Statement—Checklist of items that should be included in reports of cohort studies

Section/Topic	Item #	Recommendation	Reported on page #
Title and abstract	1	(a) Indicate the study’s design with a commonly used term in the title or the abstract	3
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	3
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	6
Objectives	3	State specific objectives, including any prespecified hypotheses	7
Methods			
Study design	4	Present key elements of study design early in the paper	7
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	7
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up	7; Figure S1, and table S1
		(b) For matched studies, give matching criteria and number of exposed and unexposed	N/A
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	Pages 7 to 10
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	Pages 7 to 10
Bias	9	Describe any efforts to address potential sources of bias	Pages 10 & 11
Study size	10	Explain how the study size was arrived at	12; Figure S1
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	Pages 7 to 10
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	Pages 10 & 11
		(b) Describe any methods used to examine subgroups and interactions	Pages 10 & 11
		(c) Explain how missing data were addressed	Pages 10 & 11
		(d) If applicable, explain how loss to follow-up was addressed	Pages 10 & 11
		(e) Describe any sensitivity analyses	Pages 10 & 11

Results				
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed		12
		(b) Give reasons for non-participation at each stage		N/A
		(c) Consider use of a flow diagram		Figure 1
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders		12; Table 1 and table S1 & S2
		(b) Indicate number of participants with missing data for each variable of interest		12
		(c) Summarise follow-up time (eg, average and total amount)		12
Outcome data	15*	Report numbers of outcome events or summary measures over time		12; Table S2
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(b) Report category boundaries when continuous variables were categorized		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period		
Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses		Pages 13 & 14; Supplementary Tables S3 to S8
Discussion				
Key results	18	Summarise key results with reference to study objectives		14
Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision.		pages 17 & 18
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence		Pages 14 to 18
Generalisability	21	Discuss the generalisability (external validity) of the study results		pages 17 & 18
Other information				
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on		2

	which the present article is based	
--	------------------------------------	--

*Give information separately for cases and controls in case-control studies and, if applicable, for exposed and unexposed groups in cohort and cross-sectional studies.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). ABSTRACT

Objective: The Mediterranean diet has been promoted as a healthy dietary pattern but, whether the Mediterranean diet may help to prevent hepatic steatosis is not clear. This study aimed to evaluate the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis.

Design: Population-based prospective cohort study.

Setting: The Swiss CoLaus study.

Participants: We evaluated 2288 adults (65.4% women, aged 55.8 ± 10.0 years) without hepatic steatosis at first follow-up in 2009-2012. Adherence to the Mediterranean diet was scaled as the Mediterranean diet score (MDS) based on the Mediterranean-diet Pyramid ascertained with responses to food-frequency questionnaires.

Outcome measures: New onset of hepatic steatosis was ascertained by two indices separately: the fatty liver index (FLI, ≥ 60 points) and the non-alcoholic fatty liver disease (NAFLD) score (≥ 0.640 points). Prospective associations between adherence to the Mediterranean diet and risk of hepatic steatosis were quantified using Poisson regression.

Results: During a mean 5.3-years of follow-up, hepatic steatosis was ascertained in 153 (6.7%) participants by FLI criteria and in 208 (9.1%) by NAFLD-score. After multivariable adjustment, higher adherence to MDS was associated with lower risk of hepatic steatosis based on FLI: risk ratio (95% confidence interval) 0.84 (0.73, 0.96) per one standard deviation of MDS; 0.85 (0.73, 0.99) adjusted for BMI; and 0.85 (0.71, 1.02) adjusted for both BMI and waist circumference. When using NAFLD-score, no significant association was found between MDS and risk of hepatic steatosis [0.95 (0.83, 1.09)].

Conclusion: A potential role of the Mediterranean diet in the prevention of hepatic steatosis is suggested by the inverse association observed between adherence to the Mediterranean diet and incidence of hepatic steatosis based on the FLI. The inconsistency of this association

STRENGTHS AND LIMITATION OF THE STUDY

- This study had the benefit of a relatively large sample size and an average of 5.3 years of follow-up.
- We applied a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean population.
- Our ascertainment of hepatic steatosis was based on two indices that has been validated for use in large epidemiological studies.
- The precision of the two hepatic steatosis indices used is different and may be influenced by the presence of steatohepatitis or advanced liver fibrosis.
- Generalisability is limited because our findings relate to a single European population.

INTRODUCTION

Hepatic steatosis is the most common cause of liver disease [1]. In westernized countries, hepatic steatosis affects up to 34% of the general population and up to 74% of obese individuals, depending on the definition used [2–4]. Hepatic steatosis—fat content of more than 5% of liver volume—is the first recognizable stage of non-alcoholic fatty liver disease (NAFLD) [1]. Hepatic steatosis, particularly NAFLD, may progress to end-stage liver disease including fibrosis, cirrhosis, and hepatocellular carcinoma [5]. Moreover, as hepatic steatosis increases the risk of metabolic syndrome, type 2 diabetes, and cardiovascular disease (CVD), its prevention is of public health importance [6]. An unhealthy dietary pattern remains one of the primary targets of lifestyle modification for the prevention and management of hepatic steatosis and NAFLD [7,8].

The Mediterranean diet has been recently recommended for treatment of NAFLD [9]. In recent years, a growing body of evidence supports the idea that the Mediterranean diet may be the reference nutritional profile for the prevention of hepatic steatosis development [10–12]. Adherence to the Mediterranean diet has been reported to have a beneficial impact on risks of CVD [13,14], type 2 diabetes [15], and metabolic syndrome [16]. Trial evidence demonstrated the potential benefits of the Mediterranean diet against progress of hepatic steatosis focusing on individuals with existing hepatic steatosis, either alone [17–22] or associated with metabolic risk factors such as obesity or diabetes [22–25]. Research among those without clinically manifest hepatic steatosis is restricted to observational evidence, reporting an inverse association that greater adherence to a Mediterranean diet is associated with lower prevalence of hepatic steatosis [26,27]. However, the cross-sectional design of these studies limits inference for causal associations and can be used mainly for hypothesis generation. Relevant longitudinal evidence for the primary prevention of hepatic steatosis or NAFLD has been reported only by the Framingham Heart Study, with a significant inverse

association of adherence to the Mediterranean diet with risk of hepatic steatosis in 1521 adults over 6 years of follow-up [28], but evidence is lacking in Europe.

Given the limited evidence from population-based epidemiological studies thus far, we aimed to investigate the prospective association between adherence to the Mediterranean diet and the risk of developing hepatic steatosis among adults without clinically manifest hepatic steatosis. We hypothesized that greater adherence to the Mediterranean diet would reduce the risk of hepatic steatosis.

METHODS

Study population

We evaluated participants in the CoLaus study, an ongoing population-based cohort investigating the clinical, biological, and genetic determinants of CVD in the city of Lausanne, Switzerland [29]. Inclusion criteria of the recruitment were adults of European origin, aged 35 to 75 years [29]. There were three study phases: baseline recruitment in 2003-2006 (n=6733), the first follow-up in 2009-2012 (n=5064), and the second follow-up in 2014-2017 (n=4881). We conducted dietary assessment at the first follow-up and therefore considered the first follow-up as the study baseline. Fatty liver index (FLI) and NAFLD-score, two indices of hepatic steatosis, were available at baseline [27]. If participants met the joint criterion of $FLI \geq 60$ or $NAFLD\text{-score} \geq -0.640$ at baseline, we excluded them as prevalent cases (see below) (n=2036). We also excluded participants with missing information on diet, outcome, and covariates (n=740) (**Figure S1**).

Patient and public involvement

Patients and/or the public were not involved in the design, conduct, reporting or dissemination plans of this research.

Dietary assessment

Participants completed a self-administered, 97-item, semi-quantitative food frequency questionnaire (FFQ) about their habitual dietary intake over the last four weeks [30], the validity of which had been assessed in canton Geneva against 24-hour recalls [30,31]. For each item, participants were instructed to report consumption frequencies by selecting one of the seven frequency options from “less than once during the last 4 weeks” to “2 or more times per day” and by selecting a usual serving size (smaller, equal, or bigger to a reference size).

Mediterranean diet scores

We derived the pyramid-based Mediterranean diet score (MDS) as a measure of adherence to the Mediterranean diet from responses to the FFQ as we conducted previously [27]. This MDS is based on the Mediterranean Dietary Pyramid proposed by the Mediterranean Diet Foundation for both Mediterranean and non-Mediterranean countries and accounting for the traditional Mediterranean diet, contemporary lifestyle, and food environment [32]. We have previously reported that this MDS scoring algorithm predicted CVD incidence [33], as well as the prevalence of hepatic steatosis [27] in non-Mediterranean populations. Briefly, a continuous score of 0 to 1 was assigned for each recommended level of the 15 components of the pyramid (vegetables, legumes, and fish as healthy items; red meat, processed meat, potato, and sweets as unhealthy items; and fruits, nuts, cereals, eggs, dairy, white meat, and alcoholic beverages as items for which moderate consumption was recommended). The resulting MDS ranges between 0 and 15 on a continuous scale. The MDS calculation was adjusted to an energy intake of 2000 kcal/d (8.37 MJ/day) by applying a regression-residual technique for energy adjustment to each food group variable [33,34].

Ascertainment of hepatic steatosis

Two indices of hepatic steatosis were evaluated: fatty liver index (FLI) [35] and NAFLD liver fat score [36]. FLI was calculated based on a logistic function including body-mass index (BMI), waist circumference, fasting triglycerides, and gamma-glutamyl transferase (GGT) levels as follows:

$$FLI = 1 / (1 + e^{-(0.953 \times \ln(\text{triglycerides}) + 0.139 \times \text{BMI} + 0.718 \times \ln(\text{GGT}) + 0.053 \times \text{waist circumference} - 15.745)})$$

FLI×100 ranges from 0 to 100. Presence of hepatic steatosis was defined by $FLI \geq 60$, a value with a sensitivity of 61% and a specificity of 86% [35]. FLI was tested previously in comparison to ultrasonography with an area under the receiver operating characteristic curve of 0.78 (OR 95% CI: 0.77, 0.83) [37].

The NAFLD-score was calculated based on an algorithm including a logistic function with the presence of metabolic syndrome defined by criteria of International Diabetes Federation [38], presence of type 2 diabetes, and fasting concentrations of insulin, aspartate-aminotransferase (AST), and the AST/ alanine transaminase (ALT) ratio:

$$\text{NAFLD-score} = -2.89 + 1.18 \times \text{metabolic syndrome (yes/no)} + 0.45 \times \text{type 2 diabetes (yes /no)} + 0.15 \times \text{fasting-insulin (mU/L)} + 0.04 \times \text{fasting-AST (U/L)} - 0.94 \times \text{AST/ALT}$$

Presence of hepatic steatosis was defined by a NAFLD-score ≥ -0.640 , a value with a sensitivity of 86% and a specificity of 71%, when compared to proton magnetic resonance imaging [36].

Assessment of covariates at baseline

Sociodemographic, lifestyle and health characteristics were collected by self-administered questionnaires. Age, sex, marital status, occupational status, and educational level were included as indicators of sociodemographic condition. Smoking status was classified as ‘never’, ‘former’, and ‘current’. Alcohol consumption was assessed by the

1
2
3 117 number of alcoholic beverage units consumed in the past week and further categorized as
4
5 118 ‘abstainers’ (0 unit/week), ‘moderate’ (1–21 units/week for men, 1–14 for women), and
6
7 119 ‘heavy’ (>21 units/week for men, >14 for women) drinkers (one unit corresponds to 8 g of
8
9
10 120 alcohol). Physical activity was assessed with a self-administered quantitative physical activity
11
12 121 frequency questionnaire [39]. Health characteristics included presence of metabolic syndrome
13
14 122 and family history of diabetes. Anthropometric and blood pressure measurements were
15
16 123 obtained using standard procedures and equipment as previously described [29]. Plasma
17

43 133 MDS as a measure of adherence to the Mediterranean diet was evaluated both
44
45 134 categorically (quintiles) and continuously scaled as one SD unit. The association of MDS with
46
47 135 the risk of hepatic steatosis was assessed using multivariable-adjusted Poisson regression
48
49 136 models with robust standard errors and estimating risk ratios (RRs) and 95% confidence
50
51 137 intervals (CIs). Models were adjusted for age, sex, marital status, occupational status,
52
53 138 educational level, smoking status, energy intake, total energy expenditure, and date of dietary
54
55 139 assessment (to adjust for seasonality). We further adjusted for BMI and waist circumference
56
57 140 as potential confounders or factors on the causal pathway to assess the possible impact of
58
59
60

141 overall and central adiposity on the association of the Mediterranean diet and hepatic
142 steatosis.

143 Additionally, we also adjusted for changes in BMI categories between baseline and
144 follow-up; for alcohol consumption (units/week); for clinical variables of metabolic risk
145 [blood pressure >130/85 mm Hg (yes/no), triglycerides >1.7 mmol/L (yes/no), high-density
146 lipoprotein level <1.29 mmol/L for men and <1.03 mmol/L for women (yes/no), and glucose
147 level ≥ 5.6 mmol/L (yes/no)] [38]; and for family history of diabetes and metabolic syndrome
148 (only for FLI) to examine their influence on the association of interest.

149 Possible interactions between MDS and age, sex, BMI, and alcohol consumption were
150 tested using the Wald test. Several sensitivity analyses were conducted to examine the
151 robustness of the observed findings. First, to assess the role of alcohol consumption (as
152 alcohol is a risk factor for fatty liver accumulation), we excluded the alcohol component from
153 the MDS, while adjusting for alcohol consumption as a covariate. We took the same
154 approaches for the other MDS components to assess the impact of each component on the
155 observed associations. Second, we conducted separate analyses after excluding participants
156 with BMI ≥ 30 kg/m²; implausible energy intake (<500 or >3500 kcal/day in women and <800
157 or >4000 kcal/day in men); excessive alcohol consumption; prevalent diabetes (defined as
158 glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of
159 hypoglycaemic drugs or insulin); or probable secondary causes of hepatic steatosis such as
160 hepatitis B or C, HIV, hepatotoxic, or autoimmune disease medications. We evaluated the
161 robustness of the results to an alternative definition of prevalent hepatic steatosis. While we
162 excluded participants with prevalent hepatic steatosis using the specified cut-offs of FLI or
163 NAFLD-score in the primary analysis, we used each of the two indices separately in
164 sensitivity analyses, whereby we evaluated 2652 adults in longitudinal analysis based on FLI;

60

and 2568 adults, based on NAFLD. Finally, we used more restrictive cutpoints and excluded participants with NAFLD-score ≥ -0.640 or with $FLI > 30$.

In a post-hoc analysis, due to inconsistency of the associations observed for FLI and NAFLD-score, we also calculated the hepatic steatosis index (HSI) [40] based on the ratio of AST/ALT , BMI , presence of type 2 diabetes, and sex:

$$HSI = 8 * AST/ALT + BMI + 2 \text{ (presence of diabetes)} + 2 \text{ (if women)}$$

Presence of hepatic steatosis was defined by a $HSI > 36$. After excluding participants with $HSI > 36$ at baseline ($n = 2674$), we evaluated 2351 adults.

In a post-hoc analysis pertaining to sensitivity of the results to model covariates and for better understanding of potential mechanisms, longitudinal associations of MDS with follow-up measures of log-transformed GGT , ALT , and AST levels and with changes in BMI and waist circumference from baseline to follow-up were examined using multivariable-adjusted linear regression. These results were expressed as β coefficient (95% CI s) for changes in each measure per 1-SD difference in MDS .

RESULTS

Participant characteristics

Of the initial 5064 participants, 2776 (54.8%) were excluded, leaving 2288 participants (65.4% women; 55.8 ± 10.0 years) for analysis. Participants included were more likely to be women, show higher sociodemographic characteristics and lower BMI , waist circumference, liver enzymes, or prevalence of metabolic syndrome in comparison to excluded individuals (**Table S1**). Being in the highest quintile of MDS was higher among women compared to men, positively correlated with sociodemographic characteristics, and

negatively correlated with being current smokers, heavy alcohol drinkers, and with BMI, waist circumference, GGT, and TG (**Table 1**).

Adherence to the Mediterranean diet and risk of hepatic steatosis

After a mean 5.3 (SD: 0.5) years of follow-up, there were 153 (6.7%) and 208 (9.1%) participants with hepatic steatosis based on FLI and NAFLD-score, respectively (**Table S2**). Case identification by FLI and NAFLD-score was modestly concordant ($\kappa=0.60$).

Multivariable-adjusted analysis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on FLI ($p_{\text{trend}} < 0.006$) with RR (95% CI) comparing the top to the bottom category of 0.50 (0.28, 0.91). The inverse associations across quintiles of MDS weakened after adjustment for BMI ($p_{\text{trend}} = 0.031$) or both BMI and waist circumference ($p_{\text{trend}} = 0.034$) (**Table 2**): RR (95% CI) = 0.61 (0.34, 1.09) and 0.60 (0.34, 1.08), respectively. In analyses using MDS as a continuous variable, the inverse association with risk of hepatic steatosis based on FLI [RR 0.84 (0.73, 0.96) per one SD of MDS] remained unchanged but getting imprecise after adjustment for BMI [RR 0.85 (0.73, 0.99)] and adjustment for both BMI and waist circumference [0.85 (0.71, 1.02)]. In sensitivity analysis, the magnitude of the inverse associations little changed after further adjustment for alcohol consumption, presence of metabolic syndrome, changes in BMI categories or clinical variables (medication use or prevalent diseases), while adjustment for BMI and clinical variables increased standard errors (**Table S3**).

Conversely, there was no association between MDS and the risk of hepatic steatosis defined by NAFLD-score criteria, with RRs (95% CIs) ranging from 0.93 (0.82, 1.05) to 1.00 (0.86, 1.17) over different regression models (**Table 2** and **Table S3**).

Interaction and sensitivity analyses

1
2
3 210 No significant interactions were found between MDS and age, sex, BMI, or alcohol
4
5 211 consumption on risk of hepatic steatosis ($p_{\text{interaction}} > 0.05$; results not shown). The contribution
6
7 212 of each component of the MDS on risk of hepatic steatosis was assessed by sequential
8
9 213 subtraction of components from the score (**Figure 1**). Excluding the components of the MDS
10
11 214 did not substantially affect the inverse associations with hepatic steatosis based on FLI; the
12
13 215 magnitude of the associations remained reasonably stable, but it became weaker ($p > 0.05$)
14
15 216 after excluding fruits, cereals, dairy products, red or processed meat, or alcohol.
16
17
18
19

20 217 In sensitivity analyses, when excluding the alcohol component from the MDS but
21
22 218 adjusting for alcohol consumption as a covariate, the inverse associations between MDS and
23
24 219 risk of hepatic steatosis based on FLI became weaker (**Table S4**). The primary results were
25
26 220 not different when excluding participants with $\text{BMI} \geq 30 \text{ kg/m}^2$, excessive alcohol
27
28 221 consumption, or secondary causes of hepatic steatosis (**Table S4**). Excluding participants with
29
30 222 implausible energy intakes weakened the associations (**Table S4**). The analysis of an
31
32 223 alternative definition of prevalent hepatic steatosis, excluding participants with only high FLI
33
34 224 score at baseline, did not alter the significant inverse association between MDS and risk of
35
36 225 FLI-based hepatic steatosis (**Table S5**). In post-hoc analyses, there was an inverse association
37
38 226 between MDS quintiles and risk of hepatic steatosis based on HSI ($p_{\text{trend}} = 0.070$) with RR
39
40 227 (95% CI) comparing the top to the bottom category of 0.70 (0.55, 0.91); a significant inverse
41
42 228 association with HSI was observed per one SD increase in MDS [RR 0.90 (0.82, 0.98)]
43
44 229 (**Table S5**). Effect sizes were of slightly higher magnitude when excluding those with $\text{FLI} > 30$
45
46 230 or $\text{NAFLD-score} \geq -0.640$ at baseline, but CIs were wider due to smaller sample size (**Table**
47
48 231 **S6**).
49
50
51
52
53

54
55 232 For NAFLD-score, no significant associations were found in any of the sensitivity
56
57 233 analyses (**Tables S4 and S5**). The sole exception was when participants with a high NAFLD-
58
59 234 score at baseline were excluded, where an inverse association between MDS quintiles and risk
60

of hepatic steatosis was present ($p_{\text{trend}}=0.039$), but this association was attenuated to the null after adjustment for BMI (**Table S5**).

Longitudinal analyses for adiposity and markers of hepatic function

In post-hoc exploratory analyses there were inverse associations of MDS with changes in BMI [β coefficient (95% CIs) per one SD higher MDS of -0.08 (-0.15, -0.02)] and in waist circumference [-0.33 (-0.61, -0.06)] (**Table S7**). For the markers of hepatic function, MDS showed a trend toward inverse association with GGT levels ($p_{\text{trend}}=0.047$) [β coefficient (95% CIs) per one SD higher MDS of -1.66 (-3.73, 0.41)], but not with ALT or AST levels (**Table S8**).

DISCUSSION

In this first population-based European study among adults free from clinically manifest hepatic steatosis to report on the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis, we found an inverse association between MDS and risk of hepatic steatosis based on FLI criteria. This relationship was attenuated to the null when controlled for general and central adiposity assessed by the BMI and waist circumference. In contrast, there was no association between adherence to the Mediterranean diet and risk of hepatic steatosis based on NAFLD-score criteria.

Current findings in context of other evidence

Our finding based on FLI is consistent with the only published prospective study relating the Mediterranean diet to hepatic steatosis, where each SD increase in MDS was estimated to decrease the odds for incident hepatic steatosis by 26% (95% CI 10%-39%) [28]. By contrast, the point estimate of the effect size in our study was smaller [(16% (95% CI 4%-27%)). A possible explanation partly lies in methodological differences. We used biochemical

and anthropometric markers to estimate hepatic steatosis in the current study, while the previous study used computed tomography assessment.

No association was found between adherence to the Mediterranean diet and risk of hepatic steatosis based on the NAFLD-score. For possible explanations based on the differences in their components, the FLI includes GGT, while NAFLD-score includes AST and AST/ALT ratio; the FLI includes adiposity markers, while the NAFLD-score does not; the FLI includes a lipid marker (triglycerides) while NAFLD-score includes markers of glycaemic status. Previous studies showed a modest association of GGT and ALT (but not AST) with the prevalence of hepatic steatosis [1]. Indeed, our analysis showed an inverse association between MDS and GGT levels, but not with AST or ALT, and these findings could explain the discrepancy between the two indices. Notably, our sensitivity analyses using different definitions of hepatic steatosis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on NAFLD-score after excluding participants with high baseline NAFLD-score only. This could be explained by modest concordance between the two measures. Of note, there were no statistically significant associations between MDS and risk of hepatic steatosis based on FLI after excluding participants with FLI>30 at baseline, which led to a smaller sample size and consequently a lower statistical power in our study. In a post-hoc analysis, we found an inverse association between adherence to the Mediterranean diet and hepatic steatosis as assessed by HSI, an alternative score to detect hepatic steatosis. Although, case identification by HSI and FLI (kappa=0.27) or NAFLD-score (Kappa=0.18) was weakly concordant; our finding based on FLI is consistent with HSI. This could be explained potentially by BMI as one of the components of both FLI and HSI, highlighting the importance of obesity for incident hepatic steatosis [41].

The inverse association between MDS and risk of hepatic steatosis defined by FLI remained significant after adjusting for BMI only but became imprecise and not significant

after adjusting for both BMI and waist circumference or for changes in BMI over the follow-up period. These results suggest the collinearity between the central adiposity and hepatic steatosis as the central adiposity may partly reflect hepatic steatosis. This biologically plausible finding is in agreement with previous cross-sectional findings for MDS and prevalent hepatic steatosis in CoLaus study and the British Fenland Study we reported [27] and a study in Hong Kong [42]. Our finding that the MDS was negatively associated with an increase in BMI after 5.3 years of follow-up is consistent with the findings from the Framingham Heart Study which observed the same trend over 6-year follow-up [28]; and from Nurses' Health Study and Health Professionals' Follow-up Study evaluating 20-year longitudinal data with repeated self-reported measures of diet and adiposity measures [43].

Sequential subtraction of different components of the MDS showed that fruits, cereals, dairy products, red or processed meat, or alcohol partially accounted for the observed association. These findings agree with previous studies [26,28,44,45] including the Framingham Heart Study suggesting benefits of low consumption of red meat and high consumption of fruits or whole grains [28]; and a cross-sectional analysis from the PREDIMED study suggesting the benefit of low consumption of red meat [26]. Moreover, the Mediterranean diet is characterized by a moderate-to-high consumption of whole grains, which has been inversely associated with the likelihood of having NAFLD [46].

Possible mechanisms and implications

Hepatic steatosis is associated with a number of metabolic risk factors including insulin resistance, type 2 diabetes, dyslipidaemia, metabolic syndrome, and oxidative stress [47]. Mediterranean-diet associated phenolic compounds (phenolic acids and polyphenols) found in fruits and vegetables and high levels of monounsaturated fatty acids of olive oil have been shown to inhibit *de novo* lipogenesis, improve peripheral insulin sensitivity, and reduce

1
2
3 307 cardiovascular risk mainly due to their antioxidant, anti-inflammatory, and anti-fibrotic
4
5 308 effects [18,48–51]. Moreover, different components of the Mediterranean diet, including
6
7 309 omega 3 polyunsaturated fatty acids (PUFA), fibre, and antioxidant rich-foods, are inversely
8
9
10 310 associated with hepatic steatosis [52,53]. One meta-analysis of interventional studies reported
11
12 311 that omega-3 PUFA were negatively associated with hepatic steatosis [54]. The
13
14 312 Mediterranean diet is also low in saturated fat, which has been demonstrated to increase
15
16 313 hepatic triglycerides content and hepatic insulin resistance [55,56]. Finally, the high fibre
17
18 314 content of the Mediterranean diet has been associated with reduced hepatic fat [18,52].
19
20
21

22 315 Hepatic steatosis is associated with cardiometabolic diseases and substantially impacts
23
24 316 public health [13,15,16]. Thus, our finding of an inverse association between adherence to the
25
26 317 Mediterranean diet and risk of hepatic steatosis would support the importance of dietary
27
28 318 advice for the prevention of hepatic steatosis as well as its treatment. However, future work
29
30 319 should confirm whether or not the clinical importance of the Mediterranean diet for the
31
32 320 prevention of hepatic steatosis is independent of obesity or central adiposity.
33
34
35

36
37 321 Strengths and *limitations*
38
39

40 322 To our knowledge, this is the first European prospective study assessing the
41
42 323 association between the Mediterranean diet and risk of hepatic steatosis. The study had the
43
44 324 benefit of a relatively large sample size and an average of 5.3 years of follow-up, and applied
45
46 325 a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean
47
48 326 population [33].
49
50
51

52
53 327 Several limitations of this study merit consideration. Measurement error and recall
54
55 328 bias are inevitable when using self-reported dietary instruments, limiting the ability to
56
57 329 precisely measure adherence to the Mediterranean diet, although adjustment for energy intake
58
59 330 may have reduced the magnitude of measurement error [57]. We used diet data measured only
60

at baseline but recognise that intra-individual variation over time might be present which would be expected to weaken the observed associations and hence our findings may be biased towards the null. However, in CoLaus, average change in estimated total energy intake from first to second follow-up was 51 kcal/day and changes for each macronutrient (expressed as % of total energy intake) were about 1% (data not shown). Thus, dietary intake in CoLaus was relatively stable, suggesting that the lack of availability of repeat dietary measures is unlikely to alter our findings substantially.

Our ascertainment of hepatic steatosis was based on two indices, but not on liver biopsy or direct imaging assessment; hence, information bias (misdiagnosis) cannot be ruled out. Although liver biopsy is the gold standard for diagnosing hepatic steatosis, its use in apparently healthy participants would be unethical and unfeasible in a large population-based study. Further, previous studies have shown that FLI and NAFLD-score can accurately identify hepatic steatosis with good sensitivity and specificity, and these scores have been validated for use in large epidemiological studies [36,37,58,59]. But, although both FLI and NAFLD-score can indicate hepatic steatosis, their precision is variable [60]. Moreover, presence of steatohepatitis or advanced liver fibrosis could influence the relationship of FLI or NAFLD-score with hepatic steatosis [61]. Of note, our study was not designed to assess the role of adherence to the Mediterranean diet in hepatic fibrosis.

Although we adjusted for many relevant confounders and performed a series of sensitivity analyses, we cannot rule out residual confounding due to unmeasured variables or covariates measured with error. Generalisability is limited because included participants seemed to be healthier than those excluded, and our findings were obtained in a single European population. Still, they confirm the findings from a previous prospective study conducted in the US [28], and might serve as a reference for other studies.

Conclusion

Adherence to the Mediterranean diet was inversely associated with risk of hepatic steatosis based on the FLI, and the association was independent of several known risk factors. Conversely, the association was not observed when using different criteria specifying the NAFLD-score. These findings support recommendations on following the Mediterranean diet for hepatic steatosis prevention in addition to the existing evidence for its benefit for cardiovascular disease prevention. Nonetheless, the findings also highlight the need for further research with more accurate measures of hepatic steatosis to replicate these findings in different populations and settings.

Figure caption

Figure 1 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2288): sensitivity analysis to examine influence of each component of Mediterranean diet.

Abbreviations: FLI, fatty liver index; NAFLD, non-alcoholic fatty liver disease.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

Risk ratio (RR) and 95% confidence intervals (CI) were estimated per one standard deviation of MDS (overall association) or of each MDS computed after excluding one component.

* Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

Abbreviations: TEE, total energy expenditure; BMI, body mass index; iqr, interquartile range; GGT, gamma-glutamyl transferase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

* The population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score. P-values were computed by using ANOVA for continuous variables and Chi-square test for categorical variables.

† Alcohol consumption categorized as “abstainers” (0 unit/week), “moderate” (1–21 units/week for men, 1–14 for women), and “heavy drinkers” (>21 units/week for men, >14 for women).

‡ Metabolic syndrome defined according to the International Diabetic Federation (waist circumference ≥94 cm in men and ≥80 cm in women plus at least two of the following factors: serum triglycerides ≥1.70 mmol/L or specific treatment for this lipid abnormality; serum high-density lipoprotein cholesterol <1.03 mmol/L in men and <1.29 mmol/L in women or specific treatment for this lipid abnormality; systolic blood pressure ≥130 mm Hg or diastolic blood pressure ≥85 mm Hg or treatment for previously diagnosed hypertension; and fasting plasma glucose ≥5.6 mmol/L or previously diagnosed type 2 diabetes).

Table 2 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2,888).

Abbreviations: iqr, interquartile range; BMI, body mass index; WC, waist circumference; NAFLD, non-alcoholic fatty liver disease

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

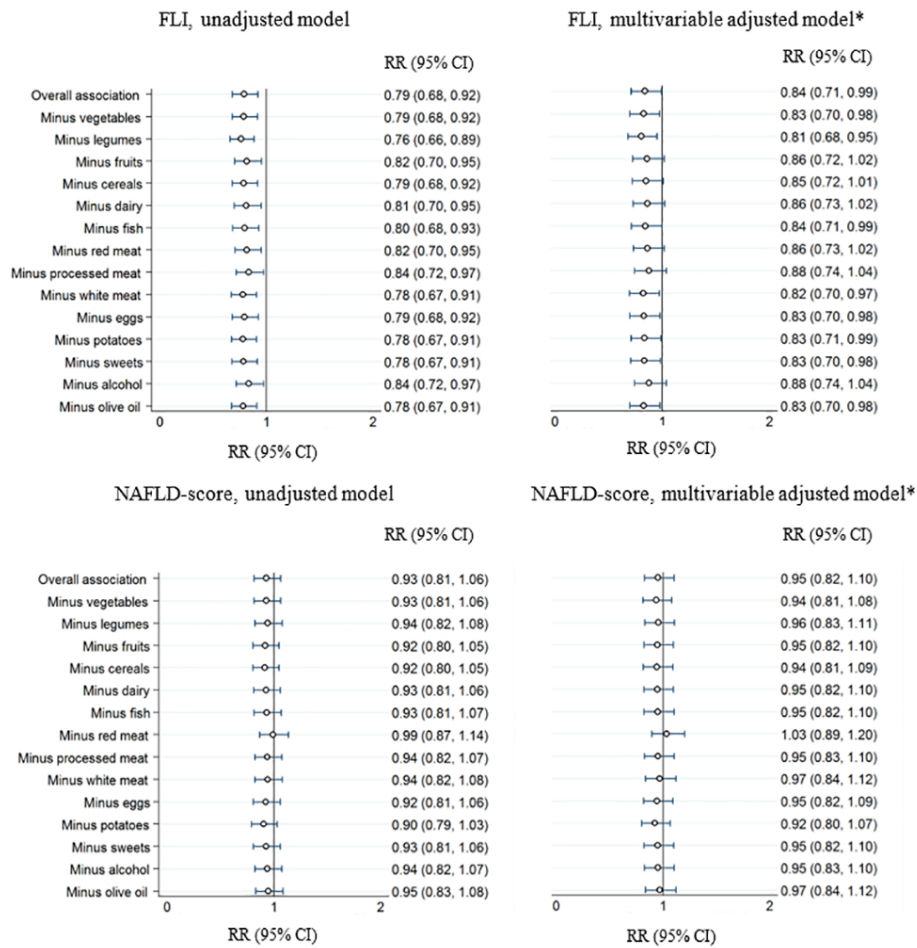

Figure 1 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2288): sensitivity analysis to examine influence of each component of Mediterranean diet.

Abbreviations: FLI, fatty liver index; NAFLD, non-alcoholic fatty liver disease. Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

Risk ratio (RR) and 95% confidence intervals (CI) were estimated per one standard deviation of MDS (overall association) or of each MDS computed after excluding one component.

* Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

Abbreviations: SES, socio economic status; BMI, body mass index; MD, Mediterranean Diet; NAFLD, non-alcoholic fatty liver disease; SD, standard deviation; CI, confidence interval.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.41 after excluding alcohol from Mediterranean Diet score components, 1.20 after excluding participants with BMI≥30, 1.18 after excluding participants with excessive alcohol consumption, 1.20 after excluding participants with probable implausible energy intake or after excluding participants with secondary causes of hepatic steatosis or diabetes.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Results of further adjustment for waist circumference were broadly in line with of the further adjustment for BMI (data not shown).

l Excluded 36 participants with BMI≥30 kg/m².

** Excessive alcohol consumption defined as >21 units per week for men and >14 units per weeks for women; excluded 60 participants with excess alcohol consumption (n=2228).

†† Implausible energy intake defined as <500 and <800 kcal or >3,500 or >4,000 kcal in women and men, respectively; excluded 4 participants with probable implausible energy intake (n=2247).

‡‡ Secondary causes of hepatic steatosis defined as having hepatitis B, C or HIV, and with hepatotoxic medications (Glucocorticoids, isoniazid, methotrexate, amiodarone, and tamoxifen); excluded 36 participants with probable secondary causes of hepatic steatosis (n=2252).

§§ Diabetes defined as glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of hypoglycaemic drugs or insulin; excluded 26 participants with probable secondary causes of hepatic steatosis (n=2262).

¶¶ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

Abbreviations: iqr, interquartile range; GGT, gamma-glutamyl transferase; SES, socio economic status; BMI, body mass index; WC, waist circumference; ALT, Alanine transaminase; AST, aspartate-aminotransferase.

Statistical analysis using linear regression; results are expressed as β coefficients and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

STROBE 2007 (v4) Statement—Checklist of items that should be included in reports of cohort studies

Section/Topic	Item #	Recommendation	Reported on page #
Title and abstract	1	(a) Indicate the study’s design with a commonly used term in the title or the abstract	3
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	3
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	6
Objectives	3	State specific objectives, including any prespecified hypotheses	7
Methods			
Study design	4	Present key elements of study design early in the paper	7
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	7
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up	7; Figure S1, and table S1
		(b) For matched studies, give matching criteria and number of exposed and unexposed	N/A
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	Pages 7 to 10
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	Pages 7 to 10
Bias	9	Describe any efforts to address potential sources of bias	Pages 10 & 11
Study size	10	Explain how the study size was arrived at	12; Figure S1
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	Pages 7 to 10
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	Pages 10 & 11
		(b) Describe any methods used to examine subgroups and interactions	Pages 10 & 11
		(c) Explain how missing data were addressed	Pages 10 & 11
		(d) If applicable, explain how loss to follow-up was addressed	Pages 10 & 11
		(e) Describe any sensitivity analyses	Pages 10 & 11

Results				
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed		12
		(b) Give reasons for non-participation at each stage		N/A
		(c) Consider use of a flow diagram		Figure 1
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders		12; Table 1 and table S1 & S2
		(b) Indicate number of participants with missing data for each variable of interest		12
		(c) Summarise follow-up time (eg, average and total amount)		12
Outcome data	15*	Report numbers of outcome events or summary measures over time		12; Table S2
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(b) Report category boundaries when continuous variables were categorized		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period		
Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses		Pages 13 & 14; Supplementary Tables S3 to S8
Discussion				
Key results	18	Summarise key results with reference to study objectives		14
Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision.		pages 17 & 18
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence		Pages 14 to 18
Generalisability	21	Discuss the generalisability (external validity) of the study results		pages 17 & 18
Other information				
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on		2

		which the present article is based		
--	--	------------------------------------	--	--

*Give information separately for cases and controls in case-control studies and, if applicable, for exposed and unexposed groups in cohort and cross-sectional studies.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). ABSTRACT

Objective: The Mediterranean diet has been promoted as a healthy dietary pattern but, whether the Mediterranean diet may help to prevent hepatic steatosis is not clear. This study aimed to evaluate the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis.

Design: Population-based prospective cohort study.

Setting: The Swiss CoLaus study.

Participants: We evaluated 2288 adults (65.4% women, aged 55.8 ± 10.0 years) without hepatic steatosis at first follow-up in 2009-2012. Adherence to the Mediterranean diet was scaled as the Mediterranean diet score (MDS) based on the Mediterranean-diet Pyramid ascertained with responses to food-frequency questionnaires.

Outcome measures: New onset of hepatic steatosis was ascertained by two indices separately: the fatty liver index (FLI, ≥ 60 points) and the non-alcoholic fatty liver disease (NAFLD) score (≥ 0.640 points). Prospective associations between adherence to the Mediterranean diet and risk of hepatic steatosis were quantified using Poisson regression.

Results: During a mean 5.3-years of follow-up, hepatic steatosis was ascertained in 153 (6.7%) participants by FLI criteria and in 208 (9.1%) by NAFLD-score. After multivariable adjustment, higher adherence to MDS was associated with lower risk of hepatic steatosis based on FLI: risk ratio (95% confidence interval) 0.84 (0.73, 0.96) per one standard deviation of MDS; 0.85 (0.73, 0.99) adjusted for BMI; and 0.85 (0.71, 1.02) adjusted for both BMI and waist circumference. When using NAFLD-score, no significant association was found between MDS and risk of hepatic steatosis [0.95 (0.83, 1.09)].

Conclusion: A potential role of the Mediterranean diet in the prevention of hepatic steatosis is suggested by the inverse association observed between adherence to the Mediterranean diet and incidence of hepatic steatosis based on the FLI. The inconsistency of this association

when hepatic steatosis was assessed by NAFLD-score points to the need for accurate population-level assessment of fatty liver and its physiologic markers.

Keywords: Mediterranean diet; hepatic steatosis; fatty liver disease; prospective study.

For peer review only

STRENGTHS AND LIMITATIONS OF THE STUDY

- This study had the benefit of a relatively large sample size and an average of 5.3 years of follow-up.
- We applied a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean population.
- Our ascertainment of hepatic steatosis was based on two indices that have been validated for use in large epidemiological studies.
- We used dietary data measured only once at baseline, and intra-individual variation over time might be present which may weaken the observed associations towards the null; however, dietary intake in CoLaus was relatively stable, suggesting that lack of repeated dietary measures is unlikely to alter our findings substantially.
- The precision of the two hepatic steatosis indices used is different and may be influenced by the presence of steatohepatitis or advanced liver fibrosis.

INTRODUCTION

Hepatic steatosis is the most common cause of liver disease [1]. In westernized countries, hepatic steatosis affects up to 34% of the general population and up to 74% of obese individuals, depending on the definition used [2–4]. Hepatic steatosis—fat content of more than 5% of liver volume—is the first recognizable stage of non-alcoholic fatty liver disease (NAFLD) [1]. Hepatic steatosis, particularly NAFLD, may progress to end-stage liver disease including fibrosis, cirrhosis, and hepatocellular carcinoma [5]. Moreover, as hepatic steatosis increases the risk of metabolic syndrome, type 2 diabetes, and cardiovascular disease (CVD), its prevention is of public health importance [6]. An unhealthy dietary pattern remains one of the primary targets of lifestyle modification for the prevention and management of hepatic steatosis and NAFLD [7,8].

The Mediterranean diet has been recently recommended for treatment of NAFLD [9]. In recent years, a growing body of evidence supports the idea that the Mediterranean diet may be the reference nutritional profile for the prevention of hepatic steatosis development [10–12]. Adherence to the Mediterranean diet has been reported to have a beneficial impact on risks of CVD [13,14], type 2 diabetes [15], and metabolic syndrome [16]. Trial evidence demonstrated the potential benefits of the Mediterranean diet against progress of hepatic steatosis focusing on individuals with existing hepatic steatosis, either alone [17–22] or associated with metabolic risk factors such as obesity or diabetes [22–25]. Research among those without clinically manifest hepatic steatosis is restricted to observational evidence, reporting an inverse association that greater adherence to a Mediterranean diet is associated with lower prevalence of hepatic steatosis [26,27]. However, the cross-sectional design of these studies limits inference for causal associations and can be used mainly for hypothesis generation. Relevant longitudinal evidence for the primary prevention of hepatic steatosis or NAFLD has been reported only by the Framingham Heart Study, with a significant inverse

association of adherence to the Mediterranean diet with risk of hepatic steatosis in 1521 adults over 6 years of follow-up [28], but evidence is lacking in Europe.

Given the limited evidence from population-based epidemiological studies thus far, we aimed to investigate the prospective association between adherence to the Mediterranean diet and the risk of developing hepatic steatosis among adults without clinically manifest hepatic steatosis. We hypothesized that greater adherence to the Mediterranean diet would reduce the risk of hepatic steatosis.

METHODS

Study population

We evaluated participants in the CoLaus study, an ongoing population-based cohort investigating the clinical, biological, and genetic determinants of CVD in the city of Lausanne, Switzerland [29]. Inclusion criteria of the recruitment were adults of European origin, aged 35 to 75 years [29]. There were three study phases: baseline recruitment in 2003-2006 (n=6733), the first follow-up in 2009-2012 (n=5064), and the second follow-up in 2014-2017 (n=4881). We conducted dietary assessment at the first follow-up and therefore considered the first follow-up as the study baseline. Fatty liver index (FLI) and NAFLD-score, two indices of hepatic steatosis, were available at baseline [27]. If participants met the joint criterion of $FLI \geq 60$ or $NAFLD\text{-score} \geq -0.640$ at baseline, we excluded them as prevalent cases (see below) (n=2036). We also excluded participants with missing information on diet, outcome, and covariates (n=740) (**Figure S1**).

Patient and public involvement

Patients and/or the public were not involved in the design, conduct, reporting or dissemination plans of this research.

71 *Dietary assessment*

72 Participants completed a self-administered, 97-item, semi-quantitative food frequency
73 questionnaire (FFQ) about their habitual dietary intake over the last four weeks [30], the
74 validity of which had been assessed in canton Geneva against 24-hour recalls [30,31]. For
75 each item, participants were instructed to report consumption frequencies by selecting one of
76 the seven frequency options from “less than once during the last 4 weeks” to “2 or more times
77 per day” and by selecting a usual serving size (smaller, equal, or bigger to a reference size).

78 *Mediterranean diet scores*

79 We derived the pyramid-based Mediterranean diet score (MDS) as a measure of
80 adherence to the Mediterranean diet from responses to the FFQ as we conducted previously
81 [27]. This MDS is based on the Mediterranean Dietary Pyramid proposed by the
82 Mediterranean Diet Foundation for both Mediterranean and non-Mediterranean countries and
83 accounting for the traditional Mediterranean diet, contemporary lifestyle, and food
84 environment [32]. We have previously reported that this MDS scoring algorithm predicted
85 CVD incidence [33], as well as the prevalence of hepatic steatosis [27] in non-Mediterranean
86 populations. Briefly, a continuous score of 0 to 1 was assigned for each recommended level of
87 the 15 components of the pyramid (vegetables, legumes, and fish as healthy items; red meat,
88 processed meat, potato, and sweets as unhealthy items; and fruits, nuts, cereals, eggs, dairy,
89 white meat, and alcoholic beverages as items for which moderate consumption was
90 recommended). The resulting MDS ranges between 0 and 15 on a continuous scale. The MDS
91 calculation was adjusted to an energy intake of 2000 kcal/d (8.37 MJ/day) by applying a
92 regression-residual technique for energy adjustment to each food group variable [33,34].

93 *Ascertainment of hepatic steatosis*

Two indices of hepatic steatosis were evaluated: fatty liver index (FLI) [35] and NAFLD liver fat score [36]. FLI was calculated based on a logistic function including body-mass index (BMI), waist circumference, fasting triglycerides, and gamma-glutamyl transferase (GGT) levels as follows:

$$FLI = 1 / (1 + e^{-(0.953 \times \ln(\text{triglycerides}) + 0.139 \times \text{BMI} + 0.718 \times \ln(\text{GGT}) + 0.053 \times \text{waist circumference} - 15.745)})$$

FLI×100 ranges from 0 to 100. Presence of hepatic steatosis was defined by $FLI \geq 60$, a value with a sensitivity of 61% and a specificity of 86% [35]. FLI was tested previously in comparison to ultrasonography with an area under the receiver operating characteristic curve of 0.78 (OR 95% CI: 0.77, 0.83) [37].

The NAFLD-score was calculated based on an algorithm including a logistic function with the presence of metabolic syndrome defined by criteria of International Diabetes Federation [38], presence of type 2 diabetes, and fasting concentrations of insulin, aspartate-aminotransferase (AST), and the AST/ alanine transaminase (ALT) ratio:

$$\begin{aligned} \text{NAFLD-score} = & -2.89 + 1.18 \times \text{metabolic syndrome (yes/no)} + 0.45 \times \text{type 2 diabetes (yes /no)} + 0.15 \\ & \times \text{fasting-insulin (mU/L)} + 0.04 \times \text{fasting-AST (U/L)} - 0.94 \times \text{AST/ALT} \end{aligned}$$

Presence of hepatic steatosis was defined by a NAFLD-score ≥ -0.640 , a value with a sensitivity of 86% and a specificity of 71%, when compared to proton magnetic resonance imaging [36].

Assessment of covariates at baseline

Sociodemographic, lifestyle and health characteristics were collected by self-administered questionnaires. Age, sex, marital status, occupational status, and educational level were included as indicators of sociodemographic condition. Smoking status was classified as ‘never’, ‘former’, and ‘current’. Alcohol consumption was assessed by the

1
2
3 117 number of alcoholic beverage units consumed in the past week and further categorized as
4
5 118 ‘abstainers’ (0 unit/week), ‘moderate’ (1–21 units/week for men, 1–14 for women), and
6
7 119 ‘heavy’ (>21 units/week for men, >14 for women) drinkers (one unit corresponds to 8 g of
8
9
10 120 alcohol). Physical activity was assessed with a self-administered quantitative physical activity
11
12 121 frequency questionnaire [39]. Health characteristics included presence of metabolic syndrome
13
14 122 and family history of diabetes. Anthropometric and blood pressure measurements were
15
16 123 obtained using standard procedures and equipment as previously described [29]. Plasma
17
18 124 triglycerides, high-density lipoprotein cholesterol, and glucose were measured using standard
19
20 125 enzymatic methods and ALT, AST, and GGT were measured using reference methods as
21
22 126 standardized by the International Federation of Clinical Chemistry.
23
24
25
26

27 127 *Statistical analysis*
28
29

30 128 Statistical analyses were performed using Stata (version 15; StataCorp, College
31
32 129 Station, TX, USA) with a two-sided test with $\alpha=0.05$. Descriptive statistics were obtained in
33
34 130 the participants included in this study in comparison to those excluded from this study.
35
36 131 Cohen’s kappa statistics were calculated to assess the agreement between the FLI and
37
38 132 NAFLD-score.
39
40
41
42

43 133 MDS as a measure of adherence to the Mediterranean diet was evaluated both
44
45 134 categorically (quintiles) and continuously scaled as one SD unit. The association of MDS with
46
47 135 the risk of hepatic steatosis was assessed using multivariable-adjusted Poisson regression
48
49 136 models with robust standard errors and estimating risk ratios (RRs) and 95% confidence
50
51 137 intervals (CIs). Models were adjusted for age, sex, marital status, occupational status,
52
53 138 educational level, smoking status, energy intake, total energy expenditure, and date of dietary
54
55 139 assessment (to adjust for seasonality). We further adjusted for BMI and waist circumference
56
57 140 as potential confounders or factors on the causal pathway to assess the possible impact of
58
59
60

141 overall and central adiposity on the association of the Mediterranean diet and hepatic
142 steatosis.

143 Additionally, we also adjusted for changes in BMI categories between baseline and
144 follow-up; for alcohol consumption (units/week); for clinical variables of metabolic risk
145 [blood pressure >130/85 mm Hg (yes/no), triglycerides >1.7 mmol/L (yes/no), high-density
146 lipoprotein level <1.29 mmol/L for men and <1.03 mmol/L for women (yes/no), and glucose
147 level ≥ 5.6 mmol/L (yes/no)] [38]; and for family history of diabetes and metabolic syndrome
148 (only for FLI) to examine their influence on the association of interest.

149 Possible interactions between MDS and age, sex, BMI, and alcohol consumption were
150 tested using the Wald test. Several sensitivity analyses were conducted to examine the
151 robustness of the observed findings. First, to assess the role of alcohol consumption (as
152 alcohol is a risk factor for fatty liver accumulation), we excluded the alcohol component from
153 the MDS, while adjusting for alcohol consumption as a covariate. We took the same
154 approaches for the other MDS components to assess the impact of each component on the
155 observed associations. Second, we conducted separate analyses after excluding participants
156 with BMI ≥ 30 kg/m²; implausible energy intake (<500 or >3500 kcal/day in women and <800
157 or >4000 kcal/day in men); excessive alcohol consumption; prevalent diabetes (defined as
158 glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of
159 hypoglycaemic drugs or insulin); or probable secondary causes of hepatic steatosis such as
160 hepatitis B or C, HIV, hepatotoxic, or autoimmune disease medications. We evaluated the
161 robustness of the results to an alternative definition of prevalent hepatic steatosis. While we
162 excluded participants with prevalent hepatic steatosis using the specified cut-offs of FLI or
163 NAFLD-score in the primary analysis, we used each of the two indices separately in
164 sensitivity analyses, whereby we evaluated 2652 adults in longitudinal analysis based on FLI;

60

and 2568 adults, based on NAFLD. Finally, we used more restrictive cutpoints and excluded participants with NAFLD-score ≥ -0.640 or with $FLI > 30$.

In a post-hoc analysis, due to inconsistency of the associations observed for FLI and NAFLD-score, we also calculated the hepatic steatosis index (HSI) [40] based on the ratio of AST/ALT , BMI , presence of type 2 diabetes, and sex:

$$HSI = 8 * AST/ALT + BMI + 2 \text{ (presence of diabetes)} + 2 \text{ (if women)}$$

Presence of hepatic steatosis was defined by a $HSI > 36$. After excluding participants with $HSI > 36$ at baseline ($n = 2674$), we evaluated 2351 adults.

In a post-hoc analysis pertaining to sensitivity of the results to model covariates and for better understanding of potential mechanisms, longitudinal associations of MDS with follow-up measures of log-transformed GGT , ALT , and AST levels and with changes in BMI and waist circumference from baseline to follow-up were examined using multivariable-adjusted linear regression. These results were expressed as β coefficient (95% CI s) for changes in each measure per 1-SD difference in MDS .

RESULTS

Participant characteristics

Of the initial 5064 participants, 2776 (54.8%) were excluded, leaving 2288 participants (65.4% women; 55.8 ± 10.0 years) for analysis. Participants included were more likely to be women, show higher sociodemographic characteristics and lower BMI , waist circumference, liver enzymes, or prevalence of metabolic syndrome in comparison to excluded individuals (**Table S1**). Being in the highest quintile of MDS was higher among women compared to men, positively correlated with sociodemographic characteristics, and

negatively correlated with being current smokers, heavy alcohol drinkers, and with BMI, waist circumference, GGT, and TG (**Table 1**).

Adherence to the Mediterranean diet and risk of hepatic steatosis

After a mean 5.3 (SD: 0.5) years of follow-up, there were 153 (6.7%) and 208 (9.1%) participants with hepatic steatosis based on FLI and NAFLD-score, respectively (**Table S2**). Case identification by FLI and NAFLD-score was modestly concordant ($\kappa=0.60$).

Multivariable-adjusted analysis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on FLI ($p_{\text{trend}} < 0.006$) with RR (95% CI) comparing the top to the bottom category of 0.50 (0.28, 0.91). The inverse associations across quintiles of MDS weakened after adjustment for BMI ($p_{\text{trend}} = 0.031$) or both BMI and waist circumference ($p_{\text{trend}} = 0.034$) (**Table 2**): RR (95% CI) = 0.61 (0.34, 1.09) and 0.60 (0.34, 1.08), respectively. In analyses using MDS as a continuous variable, the inverse association with risk of hepatic steatosis based on FLI [RR 0.84 (0.73, 0.96) per one SD of MDS] remained unchanged but getting imprecise after adjustment for BMI [RR 0.85 (0.73, 0.99)] and adjustment for both BMI and waist circumference [0.85 (0.71, 1.02)]. In sensitivity analysis, the magnitude of the inverse associations little changed after further adjustment for alcohol consumption, presence of metabolic syndrome, changes in BMI categories or clinical variables (medication use or prevalent diseases), while adjustment for BMI and clinical variables increased standard errors (**Table S3**).

Conversely, there was no association between MDS and the risk of hepatic steatosis defined by NAFLD-score criteria, with RRs (95% CIs) ranging from 0.93 (0.82, 1.05) to 1.00 (0.86, 1.17) over different regression models (**Table 2** and **Table S3**).

No significant interactions were found between MDS and age, sex, BMI, or alcohol consumption on risk of hepatic steatosis ($p_{\text{interaction}} > 0.05$; results not shown). The contribution of each component of the MDS on risk of hepatic steatosis was assessed by sequential subtraction of components from the score (**Figure 1**). Excluding the components of the MDS did not substantially affect the inverse associations with hepatic steatosis based on FLI; the magnitude of the associations remained reasonably stable, but it became weaker ($p > 0.05$) after excluding fruits, cereals, dairy products, red or processed meat, or alcohol.

In sensitivity analyses, when excluding the alcohol component from the MDS but adjusting for alcohol consumption as a covariate, the inverse associations between MDS and risk of hepatic steatosis based on FLI became weaker (**Table S4**). The primary results were not different when excluding participants with $\text{BMI} \geq 30 \text{ kg/m}^2$, excessive alcohol consumption, or secondary causes of hepatic steatosis (**Table S4**). Excluding participants with implausible energy intakes weakened the associations (**Table S4**). The analysis of an alternative definition of prevalent hepatic steatosis, excluding participants with only high FLI score at baseline, did not alter the significant inverse association between MDS and risk of FLI-based hepatic steatosis (**Table S5**). In post-hoc analyses, there was an inverse association between MDS quintiles and risk of hepatic steatosis based on HSI ($p_{\text{trend}} = 0.070$) with RR (95% CI) comparing the top to the bottom category of 0.70 (0.55, 0.91); a significant inverse association with HSI was observed per one SD increase in MDS [RR 0.90 (0.82, 0.98)] (**Table S5**). Effect sizes were of slightly higher magnitude when excluding those with $\text{FLI} > 30$ or $\text{NAFLD-score} \geq -0.640$ at baseline, but CIs were wider due to smaller sample size (**Table S6**).

For NAFLD-score, no significant associations were found in any of the sensitivity analyses (**Tables S4 and S5**). The sole exception was when participants with a high NAFLD-score at baseline were excluded, where an inverse association between MDS quintiles and risk

of hepatic steatosis was present ($p_{\text{trend}}=0.039$), but this association was attenuated to the null after adjustment for BMI (**Table S5**).

Longitudinal analyses for adiposity and markers of hepatic function

In post-hoc exploratory analyses there were inverse associations of MDS with changes in BMI [β coefficient (95% CIs) per one SD higher MDS of -0.08 (-0.15, -0.02)] and in waist circumference [-0.33 (-0.61, -0.06)] (**Table S7**). For the markers of hepatic function, MDS showed a trend toward inverse association with GGT levels ($p_{\text{trend}}=0.047$) [β coefficient (95% CIs) per one SD higher MDS of -1.66 (-3.73, 0.41)], but not with ALT or AST levels (**Table S8**).

DISCUSSION

In this first population-based European study among adults free from clinically manifest hepatic steatosis to report on the prospective association between adherence to the Mediterranean diet and risk of hepatic steatosis, we found an inverse association between MDS and risk of hepatic steatosis based on FLI criteria. This relationship was attenuated to the null when controlled for general and central adiposity assessed by the BMI and waist circumference. In contrast, there was no association between adherence to the Mediterranean diet and risk of hepatic steatosis based on NAFLD-score criteria.

Current findings in context of other evidence

Our finding based on FLI is consistent with the only published prospective study relating the Mediterranean diet to hepatic steatosis, where each SD increase in MDS was estimated to decrease the odds for incident hepatic steatosis by 26% (95% CI 10%-39%) [28]. By contrast, the point estimate of the effect size in our study was smaller [(16% (95% CI 4%-27%)). A possible explanation partly lies in methodological differences. We used biochemical

and anthropometric markers to estimate hepatic steatosis in the current study, while the previous study used computed tomography assessment.

No association was found between adherence to the Mediterranean diet and risk of hepatic steatosis based on the NAFLD-score. For possible explanations based on the differences in their components, the FLI includes GGT, while NAFLD-score includes AST and AST/ALT ratio; the FLI includes adiposity markers, while the NAFLD-score does not; the FLI includes a lipid marker (triglycerides) while NAFLD-score includes markers of glycaemic status. Previous studies showed a modest association of GGT and ALT (but not AST) with the prevalence of hepatic steatosis [1]. Indeed, our analysis showed an inverse association between MDS and GGT levels, but not with AST or ALT, and these findings could explain the discrepancy between the two indices. Notably, our sensitivity analyses using different definitions of hepatic steatosis showed an inverse association between MDS quintiles and risk of hepatic steatosis based on NAFLD-score after excluding participants with high baseline NAFLD-score only. This could be explained by modest concordance between the two measures. Of note, there were no statistically significant associations between MDS and risk of hepatic steatosis based on FLI after excluding participants with FLI>30 at baseline, which led to a smaller sample size and consequently a lower statistical power in our study. In a post-hoc analysis, we found an inverse association between adherence to the Mediterranean diet and hepatic steatosis as assessed by HSI, an alternative score to detect hepatic steatosis. Although, case identification by HSI and FLI (kappa=0.27) or NAFLD-score (Kappa=0.18) was weakly concordant; our finding based on FLI is consistent with HSI. This could be explained potentially by BMI as one of the components of both FLI and HSI, highlighting the importance of obesity for incident hepatic steatosis [41].

The inverse association between MDS and risk of hepatic steatosis defined by FLI remained significant after adjusting for BMI only but became imprecise and not significant

after adjusting for both BMI and waist circumference or for changes in BMI over the follow-up period. These results suggest the collinearity between the central adiposity and hepatic steatosis as the central adiposity may partly reflect hepatic steatosis. This biologically plausible finding is in agreement with previous cross-sectional findings for MDS and prevalent hepatic steatosis in CoLaus study and the British Fenland Study we reported [27] and a study in Hong Kong [42]. Our finding that the MDS was negatively associated with an increase in BMI after 5.3 years of follow-up is consistent with the findings from the Framingham Heart Study which observed the same trend over 6-year follow-up [28]; and from Nurses' Health Study and Health Professionals' Follow-up Study evaluating 20-year longitudinal data with repeated self-reported measures of diet and adiposity measures [43].

Sequential subtraction of different components of the MDS showed that fruits, cereals, dairy products, red or processed meat, or alcohol partially accounted for the observed association. These findings agree with previous studies [26,28,44,45] including the Framingham Heart Study suggesting benefits of low consumption of red meat and high consumption of fruits or whole grains [28]; and a cross-sectional analysis from the PREDIMED study suggesting the benefit of low consumption of red meat [26]. Moreover, the Mediterranean diet is characterized by a moderate-to-high consumption of whole grains, which has been inversely associated with the likelihood of having NAFLD [46].

Possible mechanisms and implications

Hepatic steatosis is associated with a number of metabolic risk factors including insulin resistance, type 2 diabetes, dyslipidaemia, metabolic syndrome, and oxidative stress [47]. Mediterranean-diet associated phenolic compounds (phenolic acids and polyphenols) found in fruits and vegetables and high levels of monounsaturated fatty acids of olive oil have been shown to inhibit *de novo* lipogenesis, improve peripheral insulin sensitivity, and reduce

1
2
3 307 cardiovascular risk mainly due to their antioxidant, anti-inflammatory, and anti-fibrotic
4
5 308 effects [18,48–51]. Moreover, different components of the Mediterranean diet, including
6
7 309 omega 3 polyunsaturated fatty acids (PUFA), fibre, and antioxidant rich-foods, are inversely
8
9
10 310 associated with hepatic steatosis [52,53]. One meta-analysis of interventional studies reported
11
12 311 that omega-3 PUFA were negatively associated with hepatic steatosis [54]. The
13
14 312 Mediterranean diet is also low in saturated fat, which has been demonstrated to increase
15
16 313 hepatic triglycerides content and hepatic insulin resistance [55,56]. Finally, the high fibre
17
18 314 content of the Mediterranean diet has been associated with reduced hepatic fat [18,52].
19
20
21

22 315 Hepatic steatosis is associated with cardiometabolic diseases and substantially impacts
23
24 316 public health [13,15,16]. Thus, our finding of an inverse association between adherence to the
25
26 317 Mediterranean diet and risk of hepatic steatosis would support the importance of dietary
27
28 318 advice for the prevention of hepatic steatosis as well as its treatment. However, future work
29
30 319 should confirm whether or not the clinical importance of the Mediterranean diet for the
31
32 320 prevention of hepatic steatosis is independent of obesity or central adiposity.
33
34
35

36
37 321 *Strengths and limitations*
38
39

40 322 To our knowledge, this is the first European prospective study assessing the
41
42 323 association between the Mediterranean diet and risk of hepatic steatosis. The study had the
43
44 324 benefit of a relatively large sample size and an average of 5.3 years of follow-up, and applied
45
46 325 a definition of the Mediterranean diet that has been shown to be valid in a non-Mediterranean
47
48 326 population [33].
49
50
51

52
53 327 Several limitations of this study merit consideration. Measurement error and recall
54
55 328 bias are inevitable when using self-reported dietary instruments, limiting the ability to
56
57 329 precisely measure adherence to the Mediterranean diet, although adjustment for energy intake
58
59 330 may have reduced the magnitude of measurement error [57]. We used diet data measured only
60

at baseline but recognise that intra-individual variation over time might be present which would be expected to weaken the observed associations and hence our findings may be biased towards the null. However, in CoLaus, average change in estimated total energy intake from first to second follow-up was 51 kcal/day and changes for each macronutrient (expressed as % of total energy intake) were about 1% (data not shown). Thus, dietary intake in CoLaus was relatively stable, suggesting that the lack of availability of repeat dietary measures is unlikely to alter our findings substantially.

Our ascertainment of hepatic steatosis was based on two indices, but not on liver biopsy or direct imaging assessment; hence, information bias (misdiagnosis) cannot be ruled out. Although liver biopsy is the gold standard for diagnosing hepatic steatosis, its use in apparently healthy participants would be unethical and unfeasible in a large population-based study. Further, previous studies have shown that FLI and NAFLD-score can accurately identify hepatic steatosis with good sensitivity and specificity, and these scores have been validated for use in large epidemiological studies [36,37,58,59]. But, although both FLI and NAFLD-score can indicate hepatic steatosis, their precision is variable [60]. Moreover, presence of steatohepatitis or advanced liver fibrosis could influence the relationship of FLI or NAFLD-score with hepatic steatosis [61]. Of note, our study was not designed to assess the role of adherence to the Mediterranean diet in hepatic fibrosis.

Although we adjusted for many relevant confounders and performed a series of sensitivity analyses, we cannot rule out residual confounding due to unmeasured variables or covariates measured with error. On the other hand, our adjustment for BMI and WC as markers of general and central adiposity may potentially be an over-adjustment if adiposity is on the causal pathway between dietary adherence and hepatic steatosis. However, since FLI may approximate hepatic steatosis with a degree of imprecision, adjusting for adiposity in these analyses may not represent adjusting the association between diet and steatosis directly,

but through a hepatic steatosis index that already includes adiposity measures in its definition. Nevertheless, our analytical approach is comprehensive, showing the results for crude analyses, followed by multivariable adjustment without and with further adjustment for adiposity markers. Future research with repeat measurements should further investigate this issue. Generalisability of our findings is limited because included participants seemed to be healthier than those excluded, and our findings were obtained in a single European population. Still, they confirm the findings from a previous prospective study conducted in the US [28], and might serve as a reference for other studies.

Conclusion

Adherence to the Mediterranean diet was inversely associated with risk of hepatic steatosis based on the FLI, and the association was independent of several known risk factors. Conversely, the association was not observed when using different criteria specifying the NAFLD-score. These findings support recommendations on following the Mediterranean diet for hepatic steatosis prevention in addition to the existing evidence for its benefit for cardiovascular disease prevention. Nonetheless, the findings also highlight the need for further research with more accurate measures of hepatic steatosis to replicate these findings in different populations and settings.

Figure caption

Figure 1 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2288): sensitivity analysis to examine influence of each component of Mediterranean diet.

Abbreviations: FLI, fatty liver index; NAFLD, non-alcoholic fatty liver disease.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

Risk ratio (RR) and 95% confidence intervals (CI) were estimated per one standard deviation of MDS (overall association) or of each MDS computed after excluding one component.

* Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

Abbreviations: TEE, total energy expenditure; BMI, body mass index; iqr, interquartile range; GGT, gamma-glutamyl transferase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

* The population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score. P-values were computed by using ANOVA for continuous variables and Chi-square test for categorical variables.

† Alcohol consumption categorized as “abstainers” (0 unit/week), “moderate” (1–21 units/week for men, 1–14 for women), and “heavy drinkers” (>21 units/week for men, >14 for women).

‡ Metabolic syndrome defined according to the International Diabetic Federation (waist circumference ≥94 cm in men and ≥80 cm in women plus at least two of the following factors: serum triglycerides ≥1.70 mmol/L or specific treatment for this lipid abnormality; serum high-density lipoprotein cholesterol <1.03 mmol/L in men and <1.29 mmol/L in women or specific treatment for this lipid abnormality; systolic blood pressure ≥130 mm Hg or diastolic blood pressure ≥85 mm Hg or treatment for previously diagnosed hypertension; and fasting plasma glucose ≥5.6 mmol/L or previously diagnosed type 2 diabetes).

Table 2 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2,888).

Multivariable + BMI + WC	1.00 (ref.)	1.12 (0.75, 1.67)	1.17 (0.80, 1.72)	1.07 (0.70, 1.65)	0.96 (0.60, 1.53)	0.80	1.00 (0.86, 1.17)

Abbreviations: iqr, interquartile range; BMI, body mass index; WC, waist circumference; NAFLD, non-alcoholic fatty liver disease

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

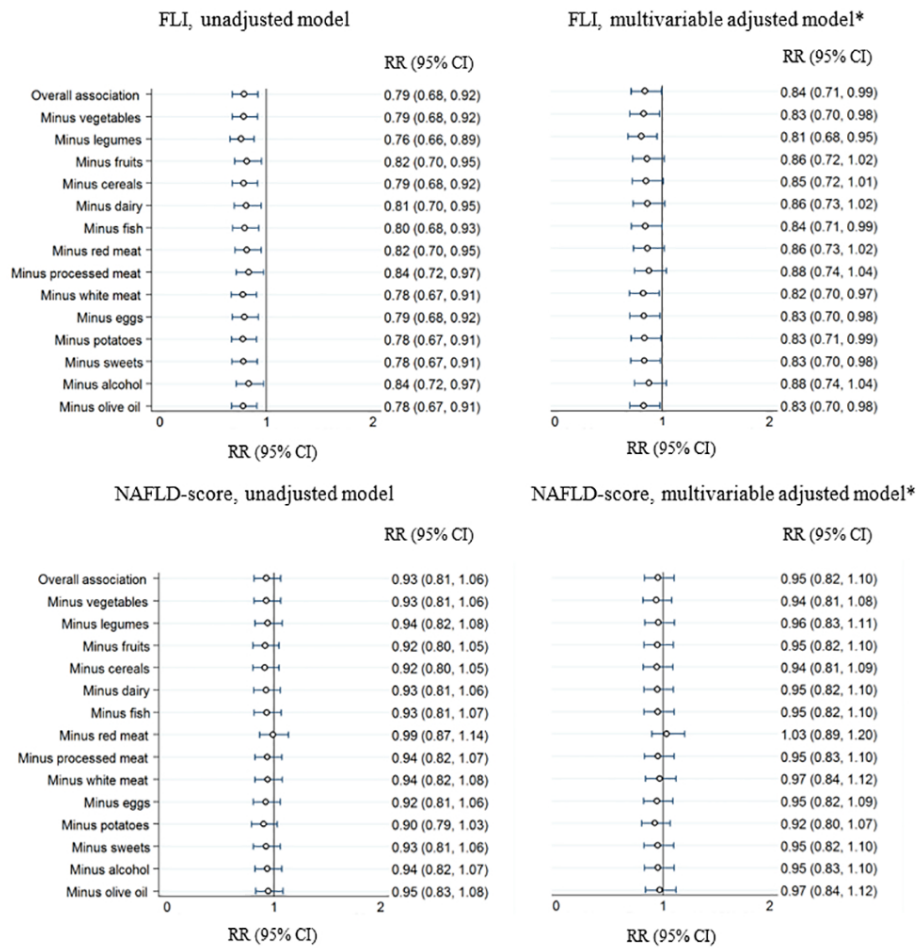

Figure 1 Prospective association of the Mediterranean diet score with the risk of hepatic steatosis, CoLaus study, Switzerland (n=2288): sensitivity analysis to examine influence of each component of Mediterranean diet.

Abbreviations: FLI, fatty liver index; NAFLD, non-alcoholic fatty liver disease. Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

Risk ratio (RR) and 95% confidence intervals (CI) were estimated per one standard deviation of MDS (overall association) or of each MDS computed after excluding one component.
* Adjusted for age (years), sex, marital status (single, married/cohabiting, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

Abbreviations: SES, socio economic status; BMI, body mass index; MD, Mediterranean Diet; NAFLD, non-alcoholic fatty liver disease; SD, standard deviation; CI, confidence interval.

Statistical analysis using Poisson regression with robust standard errors; results are expressed as risk ratios and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.41 after excluding alcohol from Mediterranean Diet score components, 1.20 after excluding participants with BMI≥30, 1.18 after excluding participants with excessive alcohol consumption, 1.20 after excluding participants with probable implausible energy intake or after excluding participants with secondary causes of hepatic steatosis or diabetes.

† Calculated based on an algorithm including BMI, waist circumference, triglycerides, and gamma-glutamyl transferase.

‡ Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

§ Results of further adjustment for waist circumference were broadly in line with of the further adjustment for BMI (data not shown).

l Excluded 36 participants with BMI≥30 kg/m².

** Excessive alcohol consumption defined as >21 units per week for men and >14 units per weeks for women; excluded 60 participants with excess alcohol consumption (n=2228).

†† Implausible energy intake defined as <500 and <800 kcal or >3,500 or >4,000 kcal in women and men, respectively; excluded 4 participants with probable implausible energy intake (n=2247).

‡‡ Secondary causes of hepatic steatosis defined as having hepatitis B, C or HIV, and with hepatotoxic medications (Glucocorticoids, isoniazid, methotrexate, amiodarone, and tamoxifen); excluded 36 participants with probable secondary causes of hepatic steatosis (n=2252).
§§ Diabetes defined as glycated haemoglobin ≥ 48 mmol/mol, or fasting plasma glucose ≥ 7.0 mmol/L, or use of hypoglycaemic drugs or insulin; excluded 26 participants with probable secondary causes of hepatic steatosis (n=2262).
¶¶ Calculated based on an algorithm including presence of the metabolic syndrome and type 2 diabetes, and concentrations of fasting serum insulin, fasting serum aspartate-aminotransferase (AST), and the AST/alanine-aminotransferase ratio.

Abbreviations: iqr, interquartile range; GGT, gamma-glutamyl transferase; SES, socio economic status; BMI, body mass index; WC, waist circumference; ALT, Alanine transaminase; AST, aspartate-aminotransferase.

Statistical analysis using linear regression; results are expressed as β coefficients and (95% confidence intervals).

* In categorical analysis, the population was divided into five groups by quintiles (Q1-Q5) of the Mediterranean diet score; Standard deviation was 1.20 for the multivariable analyses.

† Adjusted for age (years), sex, marital status (single, married/cohabitant, and widowed/Separated/divorced), occupational status (working and not working), education level (university, high school, apprenticeship, and mandatory education), smoking status (never, former, and current), energy intake (kcal/day), total energy expenditure (kcal/day), and date of dietary assessment.

STROBE 2007 (v4) Statement—Checklist of items that should be included in reports of cohort studies

Section/Topic	Item #	Recommendation	Reported on page #
Title and abstract	1	(a) Indicate the study’s design with a commonly used term in the title or the abstract	3
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	3
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	6
Objectives	3	State specific objectives, including any prespecified hypotheses	7
Methods			
Study design	4	Present key elements of study design early in the paper	7
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	7
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up	7; Figure S1, and table S1
		(b) For matched studies, give matching criteria and number of exposed and unexposed	N/A
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	Pages 7 to 10
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	Pages 7 to 10
Bias	9	Describe any efforts to address potential sources of bias	Pages 10 & 11
Study size	10	Explain how the study size was arrived at	12; Figure S1
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	Pages 7 to 10
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	Pages 10 & 11
		(b) Describe any methods used to examine subgroups and interactions	Pages 10 & 11
		(c) Explain how missing data were addressed	Pages 10 & 11
		(d) If applicable, explain how loss to follow-up was addressed	Pages 10 & 11
		(e) Describe any sensitivity analyses	Pages 10 & 11

Results				
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed		12
		(b) Give reasons for non-participation at each stage		N/A
		(c) Consider use of a flow diagram		Figure 1
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders		12; Table 1 and table S1 & S2
		(b) Indicate number of participants with missing data for each variable of interest		12
		(c) Summarise follow-up time (eg, average and total amount)		12
Outcome data	15*	Report numbers of outcome events or summary measures over time		12; Table S2
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(b) Report category boundaries when continuous variables were categorized		Pages 12 & 13; Table 2, Figure 1, and supplementary Tables and Figures
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period		
Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses		Pages 13 & 14; Supplementary Tables S3 to S8
Discussion				
Key results	18	Summarise key results with reference to study objectives		14
Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision.		pages 17 & 18
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence		Pages 14 to 18
Generalisability	21	Discuss the generalisability (external validity) of the study results		pages 17 & 18
Other information				
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on		2

		which the present article is based		
--	--	------------------------------------	--	--

*Give information separately for cases and controls in case-control studies and, if applicable, for exposed and unexposed groups in cohort and cross-sectional studies.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). Information on the STROBE Initiative is available at www.strobe-statement.org.
