## BMJ Open

BMJ Open is committed to open peer review. As part of this commitment we make the peer review history of every article we publish publicly available.

When an article is published we post the peer reviewers' comments and the authors' responses online. We also post the versions of the paper that were used during peer review. These are the versions that the peer review comments apply to.

The versions of the paper that follow are the versions that were submitted during the peer review process. They are not the versions of record or the final published versions. They should not be cited or distributed as the published version of this manuscript.

BMJ Open is an open access journal and the full, final, typeset and author-corrected version of record of the manuscript is available on our site with no access controls, subscription charges or pay-per-view fees (http://bmjopen.bmj.com).

If you have any questions on BMJ Open's open peer review process please email info.bmjopen@bmj.com

## Abstract <br> Background

The ageing population and prevalence of long-term disorders with multimorbidity is a major health challenge worldwide. The associations between comorbid conditions and mortality risk are well established; however, few prospective community-based studies have reported on prior risk factors for incident hospitalisations with multimorbidity. We aimed to explore the independent associations for a range of demographic, lifestyle and physiological determinants and the likelihood of subsequent hospital incident multimorbidity.

## Methods

We examined incident hospital admissions with multimorbidity in 25014 men and women aged 40-79 in a British prospective population-based study recruited 1993-1997 and followed-up until 2019. The determinants of incident multimorbidity, defined as Charlson Comorbidity Index $\geq 3$, were investigated using multivariable models for the 10-year period 1999-2009 and repeated with independent measurements in a second 10-year period 2009-2019.

## Results

Between 1999-2009 18179 participants ( $73 \%$ of the population) had a hospital admission. Baseline 5year and 10-year incident multimorbidity were observed in $13 \%$ and $21 \%$ of participants respectively. Age per 10-year increase OR 2.19 (95\%CI 2.06-2.33) and male sex OR 1.32 (95\%CI 1.19-1.47) predicted incident multimorbidity over 10 years. In the subset free of the most serious diseases at baseline, current smoking OR 1.74 (95\%CI 1.52-2.00), BMI $>30 \mathrm{~kg} / \mathrm{m}^{2}$ OR 1.40 ( $95 \%$ CI 1.24-1.58) and physical inactivity OR 1.14 (95\%CI 1.04-1.26) were positively associated and plasma vitamin C (a biomarker of plant food intake) per SD increase OR 0.85 (95\%CI 0.81-0.89) inversely associated with incident 10-year multimorbidity after multivariable adjustment for age, sex, social class, education, alcohol consumption, systolic blood pressure and cholesterol. Results were similar when re-examined for a further time period 2009-2019.

## Conclusion

Age, male sex and potentially modifiable lifestyle behaviours including smoking, body mass index, physical inactivity and low fruit and vegetable intake were associated with increased risk of future incident hospital admissions with multimorbidity.

## Article summary

Strengths and limitations of this study

- The majority of patients in secondary care are elderly and have multiple chronic conditions.
- Multimorbidity predicts future increased mortality but most studies are conducted in individuals who access health care.
- Cross-sectional studies have reported associations with lifestyle factors but there are few prospective population-based studies of predictors of future multimorbidity.
- In this population-based prospective study, followed-up over 20 years, we examined the likelihood of hospitalisation with multimorbidity by demographic characteristics including age and sex.
- We examined the demographic, lifestyle and physiological risk factors that predict incident multimorbidity in 5 and 10-year periods spanning 20 years and identified potentially modifiable lifestyle factors such as smoking, obesity, physical inactivity and low plant food intake.

Acknowledgements: The authors would like to thank the participants, general practitioners, and staff of EPIC-Norfolk.
Contributors: KTK,NW SH and RL were involved in the conception and design of the study. RL drafted the manuscript, with support from KTK and PP. SH contributed to data interpretation. RL was responsible for external data linkage. SH and RL contributed to data collection and acquisition. All authors read and critically revised the manuscript and approved the final manuscript. RL is the guarantor. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted.

Funding: The design and conduct of the EPIC-Norfolk study and collection and management of the data was supported by programme grants from the Medical Research Council UK (G9502233, G0401527) and Cancer Research UK (C864/A8257, C864/A2883).

Competing interests: All authors have completed the ICMJE uniform disclosure form at www.icmje.org/coi_disclosure.pdf and report: RL,SH,KTK and NW report grants from MRC and CRUK during the conduct of the study; The sponsors had no role in any of the following: study design, data collection, data analysis, interpretation of data, writing of the article, decision to submit it for publication. All authors are independent of funders and sponsors and had access to all the data. No conflicts of interest were declared by any author (apart from the two grants) and they have no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: The work was approval by the East Norfolk and Waveney NHS research governance committee (2005EC07L) and the Norfolk research ethics committee (05/Q0101/191). All participants gave informed signed consent for study participation including access to medical records.

Data sharing: The authors will make the dataset available under a Data Transfer Agreement to any bona fide researcher who wishes to obtain the dataset in order to undertake a replication analysis. Although the dataset is anonymised, the breadth of the data included and the multiplicity of variables that are included in this analysis file as primary variables or confounding factors, means that provision of the dataset to other researchers without a Data Transfer Agreement would constitute a risk. Requests for data sharing/access should be submitted to the EPIC Management Committee (epic-norfolk@mrc-epid.cam.ac.uk)

Transparency: The lead author (the manuscript's guarantor) affirms that the manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned (and, if relevant, registered) have been explained.

Open access: This is an Open Access article distributed in accordance with the terms of the Creative Commons Attribution (CC BY 4.0) license, which permits others to distribute, remix, adapt and build upon this work, for commercial use, provided the original work is properly cited. See: http://creativecommons.org/licenses/by/4.0/

Patient and public involvement: The EPIC-Norfolk Study have an active Participants Advisory Panel which meets quarterly to advise on research protocols, suggest ideas and provide feedback on the research including proposed new studies and collaborations. All participants of the EPIC-Norfolk study are informed about the study through regular newsletters as well as public meetings. Information is also disseminated through local community talks in the Norfolk area and science festivals.

Exclusive licence: The Corresponding Author has the right to grant on behalf of all authors and does grant on behalf of all authors, a worldwide licence to the Publishers and its licensees in perpetuity, in all forms, formats and media (whether known
now or created in the future), to i) publish, reproduce, distribute, display and store the Contribution, ii) translate the Contribution into other languages, create adaptations, reprints, include within collections and create summaries, extracts and/or, abstracts of the Contribution, iii) create any other derivative work(s) based on the Contribution, iv) to exploit all subsidiary rights in the Contribution, v) the inclusion of electronic links from the Contribution to third party material where-ever it may be located; and, vi) licence any third party to do any or all of the above.

## Introduction

The Academy of Medical Sciences 2018 report highlighted multimorbidity as a global priority for research. Patients with multimorbidity experience reduced wellbeing and quality of life and account for a disproportionately high share of healthcare workload and costs. Management of the rising prevalence of long-term disorders is the main challenge facing health-care systems worldwide. [1-3] Multimorbidity is commonly defined as the presence of multiple diseases or conditions with a cut-off of two or more conditions [4], however there is no agreed definition or classification system, which makes the existing evidence base difficult to interpret. [1] The term comorbidity predates multimorbidity and was used to predict the effect of additional diseases for those with an index disease of interest. [5-7] The Charlson Comorbidity Index (CCI) [8] was originally created to predict mortality in hospital patients after one year and is defined using a set of 17 chronic diseases, weighted according to the risk of death. The index has been widely used with several authors suggesting extensions or modifications to the original definition [9-14] and it remains a common standard to which other systems are often compared. [15]

The associations between comorbid conditions and mortality are well established. [16-20] However, few studies have examined the determinants of incident multimorbidity rather than its consequences [21-26] since most lack detailed demographic, socioeconomic and physiological measurements in population-based men and women prior to the onset of multimorbid disease with subsequent followup. Retrospective hospital-based studies examining multimorbidity lack community-based denominators while general practice-based studies are often cross-sectional or examine mortality in already multimorbid patients. Few studies examine factors that predict the likelihood of multimorbidity rather than factors that predict risk of individual component conditions. The large majority of studies conducted to date are cross-sectional, with few prospective community-based studies able to examine incident multimorbidity from subsequent hospitalisation. [1,24,25] In this study, we examine the independent associations for a range of demographic, lifestyle and physiological determinants and the likelihood of subsequent hospital incident multimorbidity. We use the CCI over 5-year and 10-year time periods and re-examine these associations independently in a subset 12 years after baseline since health care policy and the criteria used for admission may have changed over time. We have previously reported on risk factors for hospitalisation [27-29] but here we explore in more detail hospital admissions with multimorbidity, a measure of both health service and individual burden.

## Methods

We used data from the European Prospective Investigation into Cancer in Norfolk cohort (EPIC-

Norfolk) . [30,31] 25639 men and women aged 40-79 were recruited from general practices in Norfolk, completed a lifestyle questionnaire and attended a baseline health check from 1993 to 1997. Participants were reapproached approximately 12 years later, aged 48-92 with 9814 completing a second questionnaire and 8049 attending a health check at time-point two (TP2). Figure 1 shows a flow diagram of participant numbers at various stages. The cohort was followed-up until 2019 with annual record linkage to hospital episode data. Since linkage was to national databases and migration of cohort participants was rare, there was almost no loss to follow-up.

The Charlson Comorbidity Index (CCI) is defined using a set of chronic diseases, each having an associated weight ( $1,2,3$ or 6 ) related to the risk of death. The conditions are myocardial infarction, congestive heart failure, peripheral vascular disease, cerebrovascular disease, dementia, chronic pulmonary disease, rheumatoid disease, peptic ulcer disease, liver disease, diabetes, hemiplegia or paraplegia, renal disease, cancer and AIDS/HIV. Two levels of severity are defined for liver disease, diabetes and cancer (details are shown in supplementary table S4). All comorbidities are assigned a weight of 1 except hemiplegia/paraplegia, renal disease, and malignancies (weight=2); moderate/severe liver disease (weight=3); metastatic solid tumour and AIDS/HIV (weight=6). For diseases with two levels of severity (liver disease, diabetes and cancer), the less severe version is assigned weight $=0$ if the more severe version is also present in a patient. The CCI diseases were assigned diagnosis codes using the International Classification of Diseases (ICD-10) which was used to link the CCI to hospital episode statistics (HES) records and to cohort participants. The weighted individual disease scores were totalled to create an overall score with a maximum value of 29. [8,12] CCI was measured for various outcome periods restricted to all hospital events within the given time period: at baseline, 5 -year (1999-2004) and 10-year (1999-2009) CCI and at TP2, 5 -year (20092014) and 10-year (2009-2019) CCI. Multiple admissions including the same CCI category were only counted once.

Participants attending the baseline and TP2 health examinations had their height to the nearest 0.1 cm measured using a stadiometer (Chasemores, UK) and their weight to the nearest 100 g measured in light clothing without shoes (Salter, West Bromwich, UK). Body mass index (BMI) was calculated using measured weight in kilograms divided by the square of measured height in square metres. Trained nurses obtained non-fasting blood samples by venepuncture into plain and citrate bottles. Bloods were assayed at the Department of Clinical Biochemistry, University of Cambridge, UK. Serum concentrations of total cholesterol were measured with the RA 1000 Technicon analyser (Bayer Diagnostics, Basingstoke). Plasma was stabilised in a standardised volume of metaphosphoric acid stored at $-70^{\circ} \mathrm{C}$ and vitamin C concentrations measured using a fluorometric assay within one week. [32] Systolic blood pressure was measured using an Accutorr Sphygmomanometer (Datascope Medical, Huntington, United Kingdom). Participants sat for three minutes before two measurements
were taken with the arm horizontal and held at mid-sternum level. Systolic blood pressure was defined as the average of the two measurements.

At baseline and again at TP2, participants completed a lifestyle questionnaire. Two yes/no questions were used to derive smoking status: "Have you ever smoked as much as one cigarette a day for as long as a year?" and, where a positive response was given, "Do you smoke cigarettes now?" Participants also completed questions about their employment and that of their partner with details of both current and past employment recorded. Occupational social class was defined according to the Registrar General's classification. [33,34] A list of common UK qualifications was used to establish educational attainment and participants were asked to mark all relevant qualifications. These were then categorised using the highest qualification attained. Participants were asked about their occupational and leisure physical activity. A combined score was created combining leisure and occupational elements and divided into four ordered categories with those who did not complete the question placed in the inactive category. The score was validated against energy expenditure measured by free-living heart rate monitoring with individual calibration. [35,36] Participants were asked "Are you a non-drinker/teetotaller now?" and "At present, about how many alcoholic drinks do you have each week" for various types of alcohol. Current units were calculated from the questionnaire responses with one unit equal to a half pint of beer, one glass of wine or fortified wine or a single measure of spirits. Prevalent disease was established from the question "Has the doctor ever told you that you have any of the following?" followed by a list of common conditions including "Heart attack (myocardial infarction)", "Stroke", "Cancer" and "Diabetes".

## Statistical methods

Associations were examined both including and excluding chronic disease at baseline and repeated with independent measurements at TP2 in a subset of participants using a second baseline 12 years approximately after the first. The baseline analysis excludes 625 men and women who died before 1999 while at TP2 a further 126 participants who died prior to 2009 were excluded. Dichotomous variables were created for the social class (manual and non-manual), educational attainment (high and low) at baseline and body mass index ( $>30$ and $\leq 30 \mathrm{~kg} / \mathrm{m}^{2}$ ) and usual physical activity (active and inactive) at both baseline and TP2. For social class, professional, managerial and technical and nonmanual skilled occupations were classed as non-manual while manual skilled, partly skilled and unskilled were classed as manual. For educational attainment, those with qualifications at secondary level or above where classed as high and those with no qualification as low. Hospital outcomes were categorised into five groups, "No hospital admissions", $\mathrm{CCI}=0, \mathrm{CCI}=1, \mathrm{CCI}=2$ and $\mathrm{CCI} \geq 3$. Multivariable logistic regression was used for all models comparing CCI $\leq 2$ with CCI $\geq 3$. A sensitivity analysis, using identical models to those in table 4 for the period 1999-2009, but excluding 80 participants defined as multimorbid having only one condition with a CCI weighting $\geq 3$, gave virtually identical results to table

4 (results not shown).

The numbers of individuals with missing values for covariables at baseline were: 53 BMI, 218 smoking status, 545 social class, 18 education level. The physical activity score has no missing values since those with missing data were classified as being inactive. Multiple imputation was used to estimate missing values at TP2 most apparent when participants completed questionnaires but did not attend a health examination $n=1891$. Predictive mean matching with 5 multiple imputations and 50 iterations was used with baseline and TP2 variables. All analyses were performed using the R statistical language (R Foundation for Statistical Computing, Vienna, Austria V3.5.3 with packages knitr, Gmisc, ggplot2, tidyverse, intubate, mice.) CCIs were calculated using the R package "comorbidity". [37]

## Results

Table 1 shows future 5-year and 10-year multimorbidity hospital admission rates from baseline for $\mathrm{n}=25014$ and from time-point two (TP2) for n=9814 according to demographic characteristics in the study population. Between 1999-2009 18179 participants ( $73 \%$ of the population) had a hospital admission. Baseline 5-year and 10-year incident multimorbidity were observed in $13 \%$ and $21 \%$ of participants respectively. Figure 2 shows 10 -year multimorbidity rates ( $\mathrm{CCI} \geq 2$ ) by age group and sex. More men had CCI $\geq 3$ than women and those aged $>75$ years had the highest proportion of admissions with multimorbid conditions with $30.6 \%$ at 5 years and $36.4 \%$ at 10 years. Multimorbidity rates at TP2 were similar to baseline with 5-year and 10-year incident CCI $\geq 3$ observed in $20 \%$ and $28 \%$ of participants respectively and similar rates in those $>75$ years.

Descriptive characteristics of the cohort according to 10 -year CCI are shown in table 2. Participants with higher number of admissions and longer duration of hospital stay had higher CCI, with mean duration 58 days and 13 admissions for participants with CCI $\geq 3$ during the 10 -year period.
Participants with multimorbidity admissions were more likely at baseline examination to be current smokers, less physically active, have higher body mass index (BMI) and have lower plasma vitamin C (a proxy for a diet rich in fruit and vegetables) and report various prevalent conditions.

In table 3, odds ratios are shown for 5-year and 10-year incident multimorbidity, defined as those with $C C I \geq 3$, compared with $C C I \leq 1$ or no hospital admission, adjusted age, sex, occupational social class and educational attainment in model 1. Model 2 additionally adjusts for prevalent diseases, cardiovascular disease (CVD), cancer and diabetes; model 3 adds lifestyle factors, current smoking, alcohol units per week, usual physical activity as well as BMI $>30 \mathrm{~kg} / \mathrm{m}^{2}$ and plasma vitamin C; model 4 adds systolic blood pressure and cholesterol. Age, sex and prevalent diseases were strongly associated with multimorbidity admissions in all models. The fully adjusted association of 10-year incident multimorbidity with age per 10 years increase was OR 2.19 (95\% CI 2.06-2.33), for sex OR 1.32 (95\% CI 1.19-1.47), for prevalent CVD OR 2.22 ( $95 \%$ CI 1.87-2.62), cancer OR 2.05 ( $95 \%$ CI 1.73-2.42) and diabetes OR 3.41 ( $95 \%$ CI 2.74-4.24). The risk of multimorbidity in participants with CVD at baseline is equivalent to the risk in those without CVD 10 years older. Similarly, in participants with baseline diabetes and baseline cancer, the risk equivalent to those without disease is 17 and 11 years older respectively.

$\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson $\leq 2$ or no hospital admission.

The models in table 4 are similar to those used in table 3 but rather than adjusting for prevalent disease, participants who reported heart attack, stroke, cancer or diabetes at baseline were excluded. In this subgroup of participants without known common major diseases, in addition to age and sex, current cigarette smoking OR 1.74 ( $95 \%$ CI $1.52-2.00$ ), BMI $>30 \mathrm{~kg} / \mathrm{m}^{2}$ OR 1.40 ( $95 \%$ CI 1.24-1.58) and physical inactivity OR 1.14 (95\% CI 1.04-1.26) were positively associated and plasma vitamin C OR 0.85 (95\% CI 0.81-0.89) inversely associated with incident 10-year hospital admissions with multimorbidity after multivariable adjustment for age, sex, social class, education, alcohol consumption, systolic blood pressure and cholesterol (model 3). Manual social class and educational attainment were associated with incident multimorbidity in model 1 but were attenuated in model 2 and 3. An inverse association was observed for total cholesterol while systolic blood pressure appeared to be associated but the direction of association was not consistent with the repeated analyses from TP2. There was no association for alcohol in these models. The risk of multimorbidity in current cigarette smokers is equivalent to the risk in non-smokers 7 years older, while each $20 \mu \mathrm{~mol} / \mathrm{L}$ rise in plasma vitamin C (approximately two servings of fruit and vegetables per day [38] ) corresponds to a reduction in risk equivalent risk of those 3 years younger.

$\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson $\leq 2$ or no hospital admission.

Supplementary table S1 shows the descriptive characteristics of participants at TP2 for 10-year CCI. Mean age in this subset, measured approximately 12 years after baseline, was 69.4. Hospital admissions and length of stay was similar to the baseline with multimorbid participants (CCI $\geq 3$ ) having much longer duration than those with non-multimorbid participants or those who had no hospital admissions. Multimorbid participants were inactive, had lower plasma vitamin C (reflecting a lower intake of fruit and vegetables), were current or former smokers and had prevalent disease. In supplementary table S2, multivariable models of 10-year incident multimorbidity show that prevalent diabetes, CVD and cancer are all strongly associated. After excluding prevalent disease, supplementary table S3 shows multivariate associations in a group free from the most serious diseases at TP2. Both age and male sex are associated with subsequent multimorbidity, with educational attainment, current cigarette smoking, plasma vitamin $\mathrm{C}, \mathrm{BMI}>30 \mathrm{~kg} / \mathrm{m}^{2}$ and physical inactivity all predicting future multimorbidity. Systolic blood pressure was attenuated while other factors including cholesterol were more strong associated than at baseline. Supplementary table S4 shows the ICD-10 codes corresponding to Charlson Comorbidity Index disease groups.

## Discussion

In this community-based population followed prospectively, we observed incident hospital multimorbidity admissions rates over 5-year and 10-years periods which, as expected were strongly related to increasing age. We also observed that those with multimorbid hospital admissions had substantially more days in hospital over the outcome periods. In multivariable analyses, risk of such admissions is predicted by age, male sex and several potentially modifiable factors. Participants at baseline who smoked cigarettes, had BMI $>30$, were physically inactive or had a diet low in fruit and
vegetables all had higher likelihood of having subsequent hospital admissions with multimorbidity. Measurements made on a subset of the cohort 12 years after baseline who were followed up subsequently confirmed the baseline findings while also demonstrating an association for low education level in an older cohort with incident multimorbidity.

## Strengths and limitations of study

Most studies of multimorbidity focus on its consequences and those examining risk factors for multimorbidity are largely cross-sectional. While many prospective studies have examined the relationship between baseline characteristics and specific incident diseases or mortality, establishing multimorbidity as an endpoint is more challenging. By using the Charlson Comorbidity Index to define multimorbidity, we were able to show that the chronic diseases defined by the index had considerably higher average length of stay than other conditions requiring hospitalisation and that length of stay increased with higher CCI score. The current population-based study in a defined community was able to assess incident hospital admissions with multimorbidity to enable estimates of 5-year and 10-year rates by age and sex. We were also able to document the relationship between demographic, lifestyle and physiological factors and subsequent hospitalisations for multimorbidity. The EPIC-Norfolk cohort has been followed for 20 years enabling us to examine the determinants of multimorbidity at two time-points: in mainly middle-aged participants of 40-79 years and mainly old-aged participants of 48-92 years in a sub-cohort 12 years later after major organisational changes had been made to the National Health Service (NHS). We were also able to examine associations with and without excluding participants with known prevalent conditions at baseline.

While not attempting to examine clusters or pathways of chronic disease, we have identified risk factors that predict any hospital admissions with multimorbidity. It is possible that some factors we observed will be more strongly associated with certain combinations of diseases and others less so. However, the burden of resources experienced by hospitals can best be mitigated by early public health advice, prior to the onset of disease if possible, which can only be general in nature. Our findings are in line with current public health advice such as smoking cessation, a diet containing fruit and vegetables and regular exercise and, given the huge additional burden placed on the NHS by multimorbidity, should further emphasise the need for public health advice and intervention.

Multimorbidity can be defined in a number of ways such as disease counts or using various indexes. [39] By restricting the definition to a relatively small subset of chronic conditions such as in the CCI, inevitably some conditions will not be counted. It is notable that the CCI does not include depression or mental health, asthma or respiratory diseases, epilepsy, hypothyroidism, musculoskeletal problems or atrial fibrillation, all common in a primary care setting. [40] In addition to the CCI and other commonly used systems [41], authors have used many other definitions with variable numbers of
underlying conditions and hence the prevalence of multimorbidity varies widely. However, CCI is a widely used measure of multimorbidity.

Since the CCI is weighted to predict mortality, it may be better able to assess health service burden than a simple disease count, since procedures required for higher weighted conditions will generally be more costly. However, it may be less effective as an indicator of multiple long-term conditions. Some chronic conditions such as musculoskeletal and mental health diseases not included in the CCI are nevertheless likely to require long stay inpatient care. However, increasing CCI had longer hospital length of stay in the present study and this has also been reported in several other studies. [42,43] Medical conditions such as obesity have well established links to many diseases but, as non-diseases, are not included in the CCI. The use of CCI $\geq 3$ to define multimorbidity classifies a small number of participants with one serious disease with a high CCI weight as multimorbid. However, a sensitivity excluding these people gave virtually identical results. Studies examining the longitudinal predictors of future multimorbidity generally rely on self-reported disease but our study used the CCI from linked hospital medical coding.

When examining the relationship between lifestyle factors and health outcomes, confounding will always be a limitation. Individuals who smoke, are less physically active and eat a poor diet for example, are likely to differ from those with a contrasting lifestyle with respect to other factors relating to the likelihood of future multimorbidity including their age, sex, lifestyle factors examined in this study and others unknown. However, the associations we report were consistent after multivariable adjustment for other factors. Differential mortality is another possible limitation and would occur for any of the factors examined if participants with an apparently unhealthy characteristic were more likely to have died earlier than those with the contrary healthy characteristic and hence were less likely to use hospital services for the full follow-up period. However, the results for the 5year follow-up period where very few deaths occurred were consistent with the longer 10-year followup period. While it is possible that some participants were multimorbid at baseline, we examined those with and without baseline self-reported major chronic disease.

## Comparison with other studies

Estimates of the prevalence of multimorbidity vary widely, partly due to the variety of definitions, number of diseases, weighting etc. used in studies but range from 55 to $98 \%$ in the elderly .[6] Most studies report multimorbidity associated with age and present in more than half of those aged 65 and older. [3,44] Age was strongly associated with future hospitalisation and incident multimorbidity in our study and has been reported to increase hospitalised multimorbidity in elderly patients. [45] Many studies have found that women have a higher rate of multimorbidity than men $[6,44,46-48]$, but we observed the converse with male sex strongly predicting future multimorbidity. The use of CCI in the
context of prospective hospital admissions rather than cross-sectional multimorbidity in a primary care setting may explain the higher proportion of multimorbid men. Physical-mental comorbidity is reported higher among women in primary care [49] and mental health, which is not included in the CCI, may be more likely to be treated in a primary care than in an acute hospital setting.

Despite the considerable literature relating to multimorbidity, very few studies have examined the modifiable determinants of incident multimorbidity. Incident Cancer and cardiometabolic multimorbidity was examined in a recent multi-centre study which included data from the present study [21]; pre-diagnostic healthy lifestyle behaviours were reported to be inversely associated with the risk. BMI was also reported to be associated with incident cardiometabolic multimorbidity in a pooled analysis of 16 cohort studies. [22] A Finnish study examined incident multimorbidity in both disease-free and those with baseline diabetes and CVD. [24] They reported some similar findings to the present study such as associations with cigarette smoking, physical inactivity and BMI but associations for low education level and systolic blood pressure were only found in men. Multimorbidity was defined as the five common diseases and time to event 10-year follow-up was used rather than a follow-up period approach in this study. Participants in the Finnish cohort were younger than those in EPIC-Norfolk with the oldest participant 74 years at the end of follow-up against 90 years in EPIC-Norfolk baseline and 100 years at TP2. Studies using data from an English longitudinal cohort and using self-reported disease counts to define multimorbidity reported associations in physical activity, obesity and low level of wealth and an increased risk of multimorbidity when combined with other lifestyle factors such smoking, obesity and inadequate fruit and vegetable consumption. $[25,26]$ However, they found no association with educational attainment or excess alcohol consumption. Education, which was associated in older participants at TP2 in our study, has been linked to multimorbidity in cross-sectional studies [50] and prospectively. [24] Socioeconomic status was reported to predict the development of multimorbidity throughout the life course in a Scottish longitudinal study. [51] Both educational attainment and occupational social class were attenuated in our study possibly due to the models including plasma vitamin C , also a marker of socioeconomic status. While smoking was a strong predictor, we did not find an association with alcohol drinking. However, other studies in the literature are inconsistent, with some finding no association with cigarette smoking and alcohol consumption in cross-sectional analyses [1]

## Generalisability

While hospital admissions with multimorbidity provide an objective indicator of both Health Service and individual burden of the condition, studies of hospital admissions in many countries are limited by factors relating to differential accessibility to health care such as health insurance, income and health care policy. Though not entirely free of differential accessibility, the NHS in the UK, with service free at the point of delivery for all residents, provides an opportunity to examine hospitalised multimorbidity
with fewer of these constraints. Health care policy and criteria for admission change over time, not least in the UK over the 20-year period of this study, so we examined admissions and risk factors for multimorbidity over two independent time periods using new repeated measures and found consistent results.

## Conclusions and policy implications

We observed in a long-term population-based study that age, male sex and potentially modifiable factors including smoking, body mass index, physical inactivity and a diet low in fruit and vegetables predict future incident hospitalised multimorbidity. Multimorbidity is increasingly common among elderly hospital inpatients due in part to improved efficacy of treatments and drugs. While considerable effort is being focused on the progression, disease clustering and treatment of patients with multimorbidity, there has been less attention on the long-term predictors of future incident multimorbidity. This study suggests that modest difference in lifestyles may have the potential to mitigate the future burden of multimorbidity in the population.

[^1]STROBE Statement-Checklist of items that should be included in reports of cohort studies

|  | Item <br> No | Recommendation | Page No |
| :---: | :---: | :---: | :---: |
| Title and abstract | $1$ | (a) Indicate the study's design with a commonly used term in the title or the abstract <br> (b) Provide in the abstract an informative and balanced summary of what was done and what was found | 1 <br> 2 |
| Introduction |  |  |  |
| Background/rationale | $2$ | Explain the scientific background and rationale for the investigation being reported | 5 |
| Objectives | 3 | State specific objectives, including any prespecified hypotheses | 5 |
| Methods |  |  |  |
| Study design | 4 | Present key elements of study design early in the paper | 6 |
| Setting | 5 | Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection | 6-7 |
| Participants |  | (a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up <br> (b) For matched studies, give matching criteria and number of exposed and unexposed | 6, Figure 1 Flow diagram |
| Variables | 7 | Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable | 6-7 |
| Data sources/ measurement |  | For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group | 6-7 |
| Bias | 9 | Describe any efforts to address potential sources of bias |  |
| Study size | 10 | Explain how the study size was arrived at | Figure 1 - Flow diagram |
| Quantitative variables | 11 | Explain how quantitative variables were handled in the analyses. <br> If applicable, describe which groupings were chosen and why | 8 (statistical methods) |
| Statistical methods | 12 | (a) Describe all statistical methods, including those used to control for confounding <br> (b) Describe any methods used to examine subgroups and interactions | 8 (statistical methods) |

|  | (c) Explain how missing data were addressed | 8, statistical <br> methods |  |
| :--- | :--- | :--- | :--- |
|  | (d) If applicable, explain how loss to follow-up was addressed |  |  |
|  | (e) Describe any sensitivity analyses |  |  |
| Results |  | (a) Report numbers of individuals at each stage of study-eg <br> numbers potentially eligible, examined for eligibility, confirmed <br> eligible, included in the study, completing follow-up, and <br> analysed | Figure 1 (Flow <br> diagram) |
| (b) Give reasons for non-participation at each stage |  |  |  |
|  |  | (c) Consider use of a flow diagram | (a) Give characteristics of study participants (eg demographic, <br> (Flow diagram) |

| Main results |  | (a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, $95 \%$ confidence interval). Make clear which confounders were adjusted for and why they were included <br> (b) Report category boundaries when continuous variables were categorized <br> (c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period | 10-11, Table 3, table 4 |
| :---: | :---: | :---: | :---: |
| Other analyses | 17 | Report other analyses done-eg analyses of subgroups and interactions, and sensitivity analyses | 8, <br> Supplementary <br> Table 1-4 |
| Discussion |  |  |  |
| Key results | 18 | Summarise key results with reference to study objectives | 13 |
| Limitations | 19 | Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss both direction and magnitude of any potential bias | 13,14 |
| Interpretation | 20 | Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence | 13,16 |
| Generalisability | 21 | Discuss the generalisability (external validity) of the study results | 15 |

## Other information

Funding 22 Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based
*Give information separately for exposed and unexposed groups.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at http://www.plosmedicine.org/, Annals of Internal Medicine at http://www.annals.org/, and Epidemiology at http://www.epidem.com/). Information on the STROBE Initiative is available at http://www.strobe-statement.org.

## Abstract <br> Background

The ageing population and prevalence of long-term disorders with multimorbidity is a major health challenge worldwide. The associations between comorbid conditions and mortality risk are well established; however, few prospective community-based studies have reported on prior risk factors for incident hospital admissions with multimorbidity. We aimed to explore the independent associations for a range of demographic, lifestyle and physiological determinants and the likelihood of subsequent hospital incident multimorbidity.

## Methods

We examined incident hospital admissions with multimorbidity in 25014 men and women aged 40-79 in a British prospective population-based study recruited 1993-1997 and followed-up until 2019. The determinants of incident multimorbidity, defined as Charlson Comorbidity Index $\geq 3$, were investigated using multivariable logistic regression models for the 10-year period 1999-2009 and repeated with independent measurements in a second 10-year period 2009-2019.

## Results

Between 1999-2009 18179 participants ( $73 \%$ of the population) had a hospital admission. Baseline 5-year and 10-year incident multimorbidity were observed in $6 \%$ and $12 \%$ of participants respectively. Age per 10year increase OR 2.19 (95\%CI 2.06-2.33) and male sex OR 1.32 (95\%CI 1.19-1.47) predicted incident multimorbidity over 10 years. In the subset free of the most serious diseases at baseline, current smoking OR 1.74 (95\%CI $1.52-2.00$ ), $\mathrm{BMI}>30 \mathrm{~kg} / \mathrm{m}^{2}$ OR 1.40 ( $95 \%$ CI $1.24-1.58$ ) and physical inactivity OR 1.14 (95\%CI 1.04-1.26) were positively associated and plasma vitamin C (a biomarker of plant food intake) per SD increase OR 0.85 (95\%CI 0.81-0.89) inversely associated with incident 10-year multimorbidity after multivariable adjustment for age, sex, social class, education, alcohol consumption, systolic blood pressure and cholesterol. Results were similar when re-examined for a further time period 2009-2019.

## Conclusion

Age, male sex and potentially modifiable lifestyle behaviours including smoking, body mass index, physical inactivity and low fruit and vegetable intake were associated with increased risk of future incident hospital admissions with multimorbidity.

## Article summary

Strengths and limitations of this study

- We examined future hospital admission with multimorbidity using a prospective design and a communitybased population.
- The relationship between demographic, lifestyle and physiological factors and subsequent multimorbidity was documented.
- Measurements were made at two time-points: in mainly middle-aged participants 40-79 years and mainly old-aged participants of 48-92 years.
- Participants were followed-up over 20 years allowing several time periods to be examined.
- Restricting the definition of multimorbidity to a subset of chronic conditions means some conditions will not be counted.

Acknowledgements: The authors would like to thank the participants, general practitioners, and staff of EPIC-Norfolk.

Contributors: KTK,NW SH and RL were involved in the conception and design of the study. RL drafted the manuscript, with support from KTK and PP. SH contributed to data interpretation. RL was responsible for external data linkage. SH and RL contributed to data collection and acquisition. All authors read and critically revised the manuscript and approved the final manuscript. RL is the guarantor. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted.

Funding: The design and conduct of the EPIC-Norfolk study and collection and management of the data was supported by programme grants from the Medical Research Council UK (G9502233, G0401527) and Cancer Research UK (C864/A8257, C864/A2883).

Competing interests: All authors have completed the ICMJE uniform disclosure form at www.icmje.org/coi_disclosure.pdf and report: RL,SH,KTK and NW report grants from MRC and CRUK during the conduct of the study; The sponsors had no role in any of the following: study design, data collection, data analysis, interpretation of data, writing of the article, decision to submit it for publication. All authors are independent of funders and sponsors and had access to all the data. No conflicts of interest were declared by any author (apart from the two grants) and they have no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: The work was approval by the East Norfolk and Waveney NHS research governance committee (2005EC07L) and the Norfolk research ethics committee (05/Q0101/191). All participants gave informed signed consent for study participation including access to medical records.

Data sharing: The authors will make the dataset available under a Data Transfer Agreement to any bona fide researcher who wishes to obtain the dataset in order to undertake a replication analysis. Although the dataset is anonymised, the breadth of the data included and the multiplicity of variables that are included in this analysis file as primary variables or confounding factors, means that provision of the dataset to other researchers without a Data Transfer Agreement would constitute a risk. Requests for data sharing/access should be submitted to the EPIC Management Committee (epic-norfolk@mrc-epid.cam.ac.uk)

Transparency: The lead author (the manuscript's guarantor) affirms that the manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned (and, if relevant, registered) have been explained.

Open access: This is an Open Access article distributed in accordance with the terms of the Creative Commons Attribution (CC BY 4.0) license, which permits others to distribute, remix, adapt and build upon this work, for commercial use, provided the original work is properly cited. See: http://creativecommons.org/licenses/by/4.0/

Patient and public involvement: The EPIC-Norfolk Study have an active Participants Advisory Panel which meets quarterly to advise on research protocols, suggest ideas and provide feedback on the research including proposed new studies and collaborations. All participants of the EPIC-Norfolk study are informed about the study through regular newsletters as well as public meetings. Information is also disseminated through local community talks in the Norfolk area and science festivals.

Exclusive licence: The Corresponding Author has the right to grant on behalf of all authors and does grant on behalf of all authors, a worldwide licence to the Publishers and its licensees in perpetuity, in all forms, formats and media (whether known now or created in the future), to i) publish, reproduce, distribute, display and store the Contribution, ii) translate the Contribution into other languages, create adaptations, reprints, include within collections and create summaries, extracts and/or, abstracts of the Contribution, iii) create any other derivative work(s) based on the Contribution, iv) to exploit all subsidiary rights in the Contribution, v) the inclusion of electronic links from the Contribution to third party material where-ever it may be located; and, vi) licence any third party to do any or all of the above.

## Introduction

The Academy of Medical Sciences 2018 report highlighted multimorbidity as a global priority for research. Patients with multimorbidity experience reduced wellbeing and quality of life and account for a disproportionately high share of healthcare workload and costs. Management of the rising prevalence of long-term disorders is the main challenge facing health-care systems worldwide. [1-3]

Multimorbidity is commonly defined as the presence of multiple diseases or conditions with a cut-off of two or more conditions [4], however there is no agreed definition or classification system, which makes the existing evidence base difficult to interpret. [1] The term comorbidity predates multimorbidity and was used to predict the effect of additional diseases for those with an index disease of interest. [5-7] The Charlson Comorbidity Index (CCI) [8] was originally created to predict mortality in hospital patients after one year and is defined using a set of 17 chronic diseases, weighted according to the risk of death. The index has been widely used with several authors suggesting extensions or modifications to the original definition [9-14] and it remains a common standard to which other systems are often compared. [15]

The associations between comorbid conditions and mortality are well established. [16-20] However, few studies have examined the determinants of incident multimorbidity rather than its consequences [21-26] since most lack detailed demographic, socioeconomic and physiological measurements in population-based men and women prior to the onset of multimorbid disease with subsequent follow-up. Retrospective hospital-based studies examining multimorbidity lack community-based denominators while general practice-based studies are often cross-sectional or examine mortality in already multimorbid patients. Few studies examine factors that predict the likelihood of multimorbidity rather than factors that predict risk of individual component conditions. The large majority of studies conducted to date are cross-sectional, with few prospective community-based studies able to examine incident multimorbidity from subsequent hospitalisation. [1,24,25] In this study, we examine the independent associations for a range of demographic, lifestyle and physiological determinants and the likelihood of subsequent hospital incident multimorbidity. We use the CCI over 5-year and 10-year time periods and re-examine these associations independently in a subset 12 years after baseline since health care policy and the criteria used for admission may have changed over time. We have previously reported on risk factors for hospitalisation [27-29] but here we explore in more detail hospital admissions with multimorbidity, a measure of both health service and individual burden.

## Methods

We used data from the European Prospective Investigation into Cancer in Norfolk cohort (EPIC-Norfolk). [ 30,31$] 25639$ men and women aged 40-79 were recruited from general practices in Norfolk, completed a lifestyle questionnaire and attended a baseline health check from 1993 to 1997. Participants were reapproached approximately 12 years later, aged 48-92 with 9814 completing a second questionnaire and 8049 attending a health check at time-point two (TP2). Figure 1 shows a flow diagram of participant numbers at various stages. The cohort was followed-up until 2019 with annual record linkage to hospital episode data. Since linkage was to national databases and migration of cohort participants was rare, there was almost no loss to follow-vup. only - http://bmjopen.bmj.com/site/about/guidelines.xhtml

The Charlson Comorbidity Index (CCI) is defined using a set of chronic diseases, each having an associated weight ( $1,2,3$ or 6 ) related to the risk of death. The conditions are myocardial infarction, congestive heart failure, peripheral vascular disease, cerebrovascular disease, dementia, chronic pulmonary disease, rheumatoid disease, peptic ulcer disease, liver disease, diabetes, hemiplegia or paraplegia, renal disease, cancer and AIDS/HIV. Two levels of severity are defined for liver disease, diabetes and cancer (details are shown in supplementary table S 1 ). All comorbidities are assigned a weight of 1 except hemiplegia/paraplegia, renal disease, and malignancies (weight=2); moderate/severe liver disease (weight=3); metastatic solid tumour and AIDS/HIV (weight=6). For diseases with two levels of severity (liver disease, diabetes and cancer), the less severe version is assigned weight=0 if the more severe version is also present in a patient. The CCI diseases were assigned diagnosis codes using the International Classification of Diseases (ICD-10) which was used to link the CCI to hospital episode statistics (HES) records and to cohort participants. The weighted individual disease scores were totalled to create an overall score with a maximum value of 29 . [8,12] CCI was measured for various outcome periods restricted to all hospital events within the given time period: at baseline, 5 -year (1999-2004) and 10-year (1999-2009) CCI and at TP2, 5-year (2009-2014) and 10-year (2009-2019) CCI. Multiple admissions including the same CCI category were only counted once.

Participants attending the baseline and TP2 health examinations had their height to the nearest 0.1 cm measured using a stadiometer (Chasemores, UK) and their weight to the nearest 100 g measured in light clothing without shoes (Salter, West Bromwich, UK). Body mass index (BMI) was calculated using measured weight in kilograms divided by the square of measured height in square metres. Trained nurses obtained non-fasting blood samples by venepuncture into plain and citrate bottles. Bloods were assayed at the Department of Clinical Biochemistry, University of Cambridge, UK. Serum concentrations of total cholesterol were measured with the RA 1000 Technicon analyser (Bayer Diagnostics, Basingstoke). Plasma was stabilised in a standardised volume of metaphosphoric acid stored at $-70^{\circ} \mathrm{C}$ and vitamin C concentrations measured using a fluorometric assay within one week. [32] Systolic blood pressure was measured using an Accutorr Sphygmomanometer (Datascope Medical, Huntington, United Kingdom). Participants sat for three minutes before two measurements were taken with the arm horizontal and held at mid-sternum level. Systolic blood pressure was defined as the average of the two measurements.

At baseline and again at TP2, participants completed a lifestyle questionnaire. Two yes/no questions were used to derive smoking status: "Have you ever smoked as much as one cigarette a day for as long as a year?" and, where a positive response was given, "Do you smoke cigarettes now?" Participants also completed questions about their employment and that of their partner with details of both current and past employment recorded. Occupational social class was defined according to the Registrar General's classification. [33,34] A list of common UK qualifications was used to establish educational attainment and participants were asked to mark all relevant qualifications. These were then categorised using the highest qualification attained. Participants were asked about their occupational and leisure physical activity. A combined score was created combining leisure and occupational elements and divided into four ordered categories with those who did not complete the question placed in the inactive category. The score was validated against energy expenditure measured by free-living heart rate monitoring with individual
calibration. [35,36] Participants were asked "Are you a non-drinker/teetotaller now?" and "At present, about how many alcoholic drinks do you have each week" for various types of alcohol. Current units were calculated from the questionnaire responses with one unit equal to a half pint of beer, one glass of wine or fortified wine or a single measure of spirits. Prevalent disease was established from the question "Has the doctor ever told you that you have any of the following?" followed by a list of common conditions including "Heart attack (myocardial infarction)", "Stroke", "Cancer" and "Diabetes".

## Statistical methods

Associations were examined both including and excluding chronic disease at baseline and repeated with independent measurements at TP2 in a subset of participants using a second baseline 12 years approximately after the first. The baseline analysis excludes 625 men and women who died before 1999 while at TP2 a further 126 participants who died prior to 2009 were excluded. Dichotomous variables were created for the social class (manual and non-manual), educational attainment (high and low) at baseline and body mass index ( $>30$ and $\leq 30 \mathrm{~kg} / \mathrm{m}^{2}$ ) and usual physical activity (active and inactive) at both baseline and TP2. For social class, professional, managerial and technical and non-manual skilled occupations were classed as non-manual while manual skilled, partly skilled and unskilled were classed as manual. For educational attainment, those with qualifications at secondary level or above where classed as high and those with no qualification as low. Hospital outcomes were categorised into five groups, "No hospital admissions", $\mathrm{CCI}=0, \mathrm{CCI}=1, \mathrm{CCI}=2$ and $\mathrm{CCI} \geq 3$ and hospital admissions with multimorbidity (incident multimorbidity) defined as $\mathrm{CCI} \geq 3$. Multivariable logistic regression was used for all models and compared multimorbid participants ( $\mathrm{CCI} \geq 3$ ) with those having $\mathrm{CCI} \leq 2$ or no hospital admissions. A sensitivity analysis, using identical models to those in the primary analyses for the period 1999-2009, but excluding 80 participants defined as multimorbid having only one condition with a CCI weighting $\geq 3$, gave virtually identical results (results not shown).

The numbers of individuals with missing values for covariables at baseline were: $53 \mathrm{BMI}, 218$ smoking status, 545 social class, 18 education level. The physical activity score has no missing values since those with missing data were classified as being inactive. Multiple imputation was used to estimate missing values at TP2 most apparent when participants completed questionnaires but did not attend a health examination $\mathrm{n}=1891$. Predictive mean matching with 5 multiple imputations and 50 iterations was used with baseline and TP2 variables. All analyses were performed using the $R$ statistical language ( $R$ Foundation for Statistical Computing, Vienna, Austria V3.5.3 with packages knitr, Gmisc, ggplot2, tidyverse, intubate, mice.) CCIs were calculated using the R package "comorbidity". [37]

## Results

Table 1 shows future 5-year and 10-year Charlson Comorbidity Index hospital admission rates from baseline for $\mathrm{n}=25014$ and from time-point two (TP2) for $\mathrm{n}=9814$ according to demographic characteristics in the study population. Between 1999-2009 18179 participants ( $73 \%$ of the population) had a hospital admission. Baseline 5-year and 10-year incident multimorbidity (CCI $\geq 3$ ) were observed in $6 \%$ and $12 \%$ of participants respectively. Figure 2 shows 10 -year multimorbidity rates by age group and sex. More men had CCI $\geq 3$ than women and those aged $>75$ years had the highest proportion of admissions with multimorbid For peer reviewonly - http://bmjopen.bmj.Com/site/about/guidelines.xhtml
conditions with $14.5 \%$ at 5 years and $28.8 \%$ at 10 years. Multimorbidity rates at TP2 were slightly higher than baseline with 5 -year and 10 -year incident CCI $\geq 3$ observed in $10 \%$ and $20 \%$ of participants respectively and the highest proportion in those $>75$ years.

Descriptive characteristics of the cohort according to 10 -year CCI are shown in table 2. Participants with higher number of total admissions and longer duration of hospital stay had higher CCI, with mean duration 58 days and 13 admissions for participants with CCI $\geq 3$ during the 10 -year period. Participants with multimorbidity admissions were more likely at baseline examination to be current smokers, less physically active, have higher body mass index (BMI) and have lower plasma vitamin C (a proxy for a diet rich in fruit and vegetables) and report various prevalent conditions.

In table 3, odds ratios are shown for 5-year and 10-year incident multimorbidity, defined as those with CCI $\geq 3$, compared with CCI $\leq 2$ or no hospital admission, adjusted age, sex, occupational social class and educational attainment in model 1 . Model 2 additionally adjusts for prevalent diseases, cardiovascular disease (CVD), cancer and diabetes; model 3 adds lifestyle factors, current smoking, alcohol units per week, usual physical activity as well as BMI $>30 \mathrm{~kg} / \mathrm{m}^{2}$ and plasma vitamin C; model 4 adds systolic blood pressure and cholesterol. Age, sex and prevalent diseases were strongly associated with multimorbidity admissions in all models. The fully adjusted association of 10 -year incident multimorbidity with age per 10 years increase was OR 2.19 ( $95 \%$ CI 2.06-2.33), for sex OR 1.32 ( $95 \%$ CI 1.19-1.47), for prevalent CVD OR 2.22 ( $95 \%$ CI $1.87-2.62$ ), cancer OR 2.05 ( $95 \%$ CI 1.73-2.42) and diabetes OR 3.41 ( $95 \%$ CI 2.74-4.24). The risk of multimorbidity in participants with CVD at baseline is equivalent to the risk in those without CVD 10 years older. Similarly, in participants with baseline diabetes and baseline cancer, the risk equivalent to those

For peer review only - http://bmjopen.bmj.com/site/about/guidelines.xhtml
without disease is 17 and 11 years older respectively.

$\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson Comorbidity Index $\leq 2$ or no hospital admission.

The models in table 4 are similar to those used in table 3 but rather than adjusting for prevalent disease, participants who reported heart attack, stroke, cancer or diabetes at baseline were excluded. In this subgroup of participants without known common major diseases, in addition to age and sex, current cigarette smoking OR 1.74 ( $95 \%$ CI $1.52-2.00$ ), BMI $>30 \mathrm{~kg} / \mathrm{m}^{2}$ OR 1.40 ( $95 \%$ CI $1.24-1.58$ ) and physical inactivity OR 1.14 ( $95 \%$ CI 1.04-1.26) were positively associated and plasma vitamin C OR 0.85 ( $95 \%$ CI $0.81-0.89$ ) inversely associated with incident 10-year hospital admissions with multimorbidity after multivariable adjustment for age, sex, social class, education, alcohol consumption, systolic blood pressure and cholesterol (model 3). Manual social class and educational attainment were associated with incident multimorbidity in model 1 but were attenuated in model 2 and 3 . An inverse association was observed for

not consistent with the repeated analyses from TP2. There was no association for alcohol in these models. The risk of multimorbidity in current cigarette smokers is equivalent to the risk in non-smokers 7 years older, while each $20 \mu \mathrm{~mol} / \mathrm{L}$ rise in plasma vitamin C (approximately two servings of fruit and vegetables per day [38] ) corresponds to a reduction in risk equivalent risk of those 3 years younger.

$\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson Comorbidity Index $\leq 2$ or no hospital admission.

Supplementary table S 1 shows the ICD-10 codes corresponding to Charlson Comorbidity Index disease groups. Supplementary table S2 shows the descriptive characteristics of participants at TP2 for 10-year CCI. Mean age in this subset, measured approximately 12 years after baseline, was 69.4 . Hospital admissions and length of stay was similar to the baseline with multimorbid participants (CCI $\geq 3$ ) having much longer duration than those with non-multimorbid participants or those who had no hospital admissions. Multimorbid participants were inactive, had lower plasma vitamin C (reflecting a lower intake of fruit and vegetables), were current or former smokers and had prevalent disease. In supplementary table S3, multivariable models of 10-year incident multimorbidity show that prevalent diabetes, CVD and cancer are all strongly associated. After excluding prevalent disease, supplementary table S 4 shows multivariable associations in a group free from the most serious diseases at TP2. Both age and male sex are associated with subsequent multimorbidity, with educational attainment, current cigarette smoking, plasma vitamin C, BMI $>30 \mathrm{~kg} / \mathrm{m}^{2}$ and physical inactivity all predicting future multimorbidity. Systolic blood pressure was attenuated while other factors including cholesterol were more strongly associated than at baseline.

## Discussion

In this community-based population followed prospectively, we observed incident hospital multimorbidity admissions rates over 5-year and 10-years periods which, as expected were strongly related to increasing age. We also observed that those with multimorbid hospital admissions had substantially more days in hospital over the outcome periods. In multivariable analyses, risk of such admissions is predicted by age, male sex and several potentially modifiable factors. Participants at baseline who smoked cigarettes, had BMI $>30$, were physically inactive or had a diet low in fruit and vegetables all had higher likelihood of having subsequent hospital admissions with multimorbidity. Measurements made on a subset of the cohort 12 years after baseline who were followed up subsequently confirmed the baseline findings while also demonstrating an association for low education level in an older cohort with incident multimorbidity.

## Strengths and limitations of study

Most studies of multimorbidity focus on its consequences and those examining risk factors for multimorbidity are largely cross-sectional. While many prospective studies have examined the relationship between baseline characteristics and specific incident diseases or mortality, establishing multimorbidity as an endpoint is more challenging. By using the Charlson Comorbidity Index to define multimorbidity, we were able to show that the chronic diseases defined by the index had considerably higher average length of stay than other conditions requiring hospitalisation and that length of stay increased with higher CCI score. The current population-based study in a defined community was able to assess incident hospital admissions with multimorbidity to enable estimates of 5-year and 10-year rates by age and sex. We were also able to document the relationship between demographic, lifestyle and physiological factors and subsequent hospitalisations for multimorbidity. The EPIC-Norfolk cohort has been followed for 20 years enabling us to examine the determinants of multimorbidity at two time-points: in mainly middle-aged participants of 4079 years and mainly old-aged participants of 48-92 years in a sub-cohort 12 years later after major organisational changes had been made to the National Health Service (NHS). We were also able to examine associations with and without excluding participants with known prevalent conditions at baseline.

While not attempting to examine clusters or pathways of chronic disease, we have identified risk factors that predict any hospital admissions with multimorbidity. It is possible that some factors we observed will be more strongly associated with certain combinations of diseases and others less so. However, the burden of resources experienced by hospitals can best be mitigated by early public health advice, prior to the onset of disease if possible, which can only be general in nature. Our findings are in line with current public health advice such as smoking cessation, a diet containing fruit and vegetables and regular exercise and, given the huge additional burden placed on the NHS by multimorbidity, should further emphasise the need for public health advice and intervention.

Multimorbidity can be defined in a number of ways such as disease counts or using various indexes. [39] By restricting the definition to a relatively small subset of chronic conditions such as in the CCI, inevitably some conditions will not be counted. It is notable that the CCI does not include depression or mental health, asthma or respiratory diseases, epilepsy, hypothyroidism, musculoskeletal problems or atrial fibrillation, all common in a primary care setting. [40] In addition to the CCI and other commonly used systems [41], For peer review ơily - http://bmjopen.bmj.com/site/about/guidelines.xhtml
authors have used many other definitions with variable numbers of underlying conditions and hence the prevalence of multimorbidity varies widely. However, CCI is a widely used measure of multimorbidity.

Since the CCI is weighted to predict mortality, it may be better able to assess health service burden than a simple disease count, since procedures required for higher weighted conditions will generally be more costly. However, it may be less effective as an indicator of multiple long-term conditions. Some chronic conditions such as musculoskeletal and mental health diseases not included in the CCI are nevertheless likely to require long stay inpatient care. However, increasing CCI had longer hospital length of stay in the present study and this has also been reported in several other studies. [42,43] Medical conditions such as obesity have well established links to many diseases but, as non-diseases, are not included in the CCI. The use of CCI $\geq 3$ to define multimorbidity classifies a small number of participants with one serious disease with a high CCI weight as multimorbid. However, a sensitivity excluding these people gave virtually identical results. Studies examining the longitudinal predictors of future multimorbidity generally rely on selfreported disease but our study used the CCI from linked hospital medical coding.

When examining the relationship between lifestyle factors and health outcomes, confounding will always be a limitation. Individuals who smoke, are less physically active and eat a poor diet for example, are likely to differ from those with a contrasting lifestyle with respect to other factors relating to the likelihood of future multimorbidity including their age, sex, lifestyle factors examined in this study and others unknown.
However, the associations we report were consistent after multivariable adjustment for other factors. Differential mortality is another possible limitation and would occur for any of the factors examined if participants with an apparently unhealthy characteristic were more likely to have died earlier than those with the contrary healthy characteristic and hence were less likely to use hospital services for the full followup period. However, the results for the 5 -year follow-up period where very few deaths occurred were consistent with the longer 10-year follow-up period. While it is possible that some participants were multimorbid at baseline, we examined those with and without baseline self-reported major chronic disease.

## Comparison with other studies

Estimates of the prevalence of multimorbidity vary widely, partly due to the variety of definitions, number of diseases, weighting etc. used in studies but range from 55 to $98 \%$ in the elderly. [6] Most studies report multimorbidity associated with age and present in more than half of those aged 65 and older. [3,44] Age was strongly associated with future hospitalisation and incident multimorbidity in our study and has been reported to increase hospitalised multimorbidity in elderly patients. [45] Many studies have found that women have a higher rate of multimorbidity than men [6,44,46-48], but we observed the converse with male sex strongly predicting future multimorbidity. The use of CCI in the context of prospective hospital admissions rather than cross-sectional multimorbidity in a primary care setting may explain the higher proportion of multimorbid men. Physical-mental comorbidity is reported higher among women in primary care [49] and mental health, which is not included in the CCI, may be more likely to be treated in a primary care than in an acute hospital setting.

Despite the considerable literature relating to multimorbidity, very few studies have examined the modifiable determinants of incident multimorbidity. Incident Cancer and cardiometabolic multimorbidity For peer review only - http://bmjopen.bmj.com/site/about/guidelines.xhtml
was examined in a recent multi-centre study which included data from the present study [21]; pre- diagnostic healthy lifestyle behaviours were reported to be inversely associated with the risk. BMI was also reported to be associated with incident cardiometabolic multimorbidity in a pooled analysis of 16 cohort studies. [22] A Finnish study examined incident multimorbidity in both disease-free and those with baseline diabetes and CVD. [24] They reported some similar findings to the present study such as associations with cigarette smoking, physical inactivity and BMI but associations for low education level and systolic blood pressure were only found in men. Multimorbidity was defined using five common diseases and time to event 10-year follow-up was used rather than a follow-up period approach in this study. Participants in the Finnish cohort were younger than those in EPIC-Norfolk with the oldest participant 74 years at the end of follow-up against 90 years in EPIC-Norfolk baseline and 100 years at TP2. Studies using data from an English longitudinal cohort and using self-reported disease counts to define multimorbidity reported associations in physical activity, obesity and low level of wealth and an increased risk of multimorbidity when combined with other lifestyle factors such smoking, obesity and inadequate fruit and vegetable consumption. [25,26] However, they found no association with educational attainment or excess alcohol consumption. Education, which was associated in older participants at TP2 in our study, has been linked to multimorbidity in crosssectional studies [50] and prospectively. [24] Socioeconomic status was reported to predict the development of multimorbidity throughout the life course in a Scottish longitudinal study. [51] Both educational attainment and occupational social class were attenuated in our study possibly due to the models including plasma vitamin C, also a marker of socioeconomic status. While smoking was a strong predictor, we did not find an association with alcohol drinking. However, other studies in the literature are inconsistent, with some finding no association with cigarette smoking and alcohol consumption in cross-sectional analyses [1]

## Generalisability

While hospital admissions with multimorbidity provide an objective indicator of both Health Service and individual burden of the condition, studies of hospital admissions in many countries are limited by factors relating to differential accessibility to health care such as health insurance, income and health care policy. Though not entirely free of differential accessibility, the NHS in the UK, with service free at the point of delivery for all residents, provides an opportunity to examine hospitalised multimorbidity with fewer of these constraints. Health care policy and criteria for admission change over time, not least in the UK over the 20-year period of this study, so we examined admissions and risk factors for multimorbidity over two independent time periods using new repeated measures and found consistent results.

## Conclusions and policy implications

We observed in a long-term population-based study that age, male sex and potentially modifiable factors including smoking, body mass index, physical inactivity and a diet low in fruit and vegetables predict future incident hospitalised multimorbidity. Multimorbidity is increasingly common among elderly hospital inpatients due in part to improved efficacy of treatments and drugs. While considerable effort is being focused on the progression, disease clustering and treatment of patients with multimorbidity, there has been less attention on the long-term predictors of future incident multimorbidity. This study suggests that modest difference in lifestyles may have the potential to mitigate the future burden of multimorbidity in the
population.

$\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson $\leq 2$ or no hospital admission.

STROBE Statement-Checklist of items that should be included in reports of cohort studies

Item
No

Page No
Recommendation

| Title and abstract | 1 | (a) Indicate the study's design with a commonly used term in the title <br> or the abstract | 1 |
| :--- | :--- | :--- | :--- |
|  | (b) Provide in the abstract an informative and balanced summary of <br> what was done and what was found | 2 |  |

Introduction

|  | (c) Explain how missing data were addressed <br> (d) If applicable, explain how loss to follow-up was addressed <br> (e) Describe any sensitivity analyses |  | 8, statistical methods |
| :---: | :---: | :---: | :---: |
| Results |  |  |  |
| Participants |  | (a) Report numbers of individuals at each stage of study-eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed <br> (b) Give reasons for non-participation at each stage <br> (c) Consider use of a flow diagram | Figure 1 (Flow diagram) <br> 6, Figure 1 (Flow diagram) <br> Figure 1 (Flow diagram) |
| Descriptive data | 14* | (a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders <br> (b) Indicate number of participants with missing data for each variable of interest <br> (c) Summarise follow-up time (eg, average and total amount) | 8, Table 1, Table 2, Figure 2 <br> 8, statistical methods <br> 8, Title |
| Outcome data | 15* | Report numbers of outcome events or summary measures over time | 8-9,Table1 |

| Main results |  | (a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, $95 \%$ confidence interval). Make clear which confounders were adjusted for and why they were included <br> (b) Report category boundaries when continuous variables were categorized <br> (c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period | 10-11, Table 3, table 4 |
| :---: | :---: | :---: | :---: |
| Other analyses | 17 | Report other analyses done-eg analyses of subgroups and interactions, and sensitivity analyses | 8, <br> Supplementary <br> Table 1-4 |
| Discussion |  |  |  |
| Key results | 18 | Summarise key results with reference to study objectives | 13 |
| Limitations | 19 | Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss both direction and magnitude of any potential bias | 13,14 |
| Interpretation | 20 | Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence | 13,16 |
| Generalisability | 21 | Discuss the generalisability (external validity) of the study results | 15 |

## Other information

Funding 22 Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based
*Give information separately for exposed and unexposed groups.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at http://www.plosmedicine.org/, Annals of Internal Medicine at http://www.annals.org/, and Epidemiology at http://www.epidem.com/). Information on the STROBE Initiative is available at http://www.strobe-statement.org.

[^0]:    $\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson $\leq 2$ or no hospital admission.

[^1]:    All comorbidities are assigned a weight of 1 except hemiplegia/paraplegia, renal disease, and malignancies (weight=2); moderate/severe liver disease (weight=3); metastatic solid tumour and AIDS/HIV (weight=6). For diseases with two levels of severity (liver disease, diabetes and cancer), the less severe version is assigned weight $=0$ if the more severe version is also present in a patient. Reproduced from documentation for the 'comorbidity' R package (Gasparini, 2019)

[^2]:    $\dagger$ Charlson Comorbidity Index $\geq 3$ vs Charlson Comorbidity Index $\leq 2$ or no hospital admission.
