Suicide-related discussions with depressed primary care patients in the USA: gender and quality gaps. A mixed methods analysis

Steven D Vannoy, Lynne S Robins

ABSTRACT

Objective: To characterise suicide-risk discussions in depressed primary-care patients.

Design: Secondary analysis of recordings and self reports by physicians and patients. Descriptive statistics of depression and suicide-related discussion, with qualitative extraction of disclosure, enquiry and physician response.

Participants: 48 primary-care physicians and 1776 adult patients.

Measures: Presence of depression or suicide-related discussions during the encounter; patient and physician demographics; depression symptom severity and suicide ideation as measured by the Patient Health Questionnaire (PHQ9); physician's decision-making style as measured by the Medical Outcomes Study Participatory Decision-Making Scale; support for autonomy as measured by the Health Care Climate Questionnaire; trust in their physician as measured by the Primary Care Assessment Survey; physician response to suicide-related enquiry or disclosure.

Results: Of the 1776 encounters, 128 involved patients scoring >14 on the PHQ9. These patients were seen by 43 of the 48 physicians. Suicide ideation was endorsed by 59% (n=75). Depression was discussed in 52% of the encounters (n=66). Suicide-related discussion occurred in only 11% (n=13) of encounters. 92% (n=12) of the suicide discussions occurred with patients scoring <2 on PHQ9 item 9. Suicide was discussed in only one encounter with a male. Variation in elicitation and response styles demonstrated preferred and discouraged interviewing strategies.

Conclusions: Suicide ideation is present in a significant proportion of depressed primary care patients but rarely discussed. Men, who carry the highest risk for suicide, are unlikely to disclose their ideation or be asked about it. Patient-centred communication and positive healthcare climate do not appear to increase the likelihood of suicide related discussion. Physicians should be encouraged to ask about suicide ideation in their depressed patients and, when disclosure occurs, facilitate discussion and develop targeted treatment plans.

ARTICLE SUMMARY

Article focus

- Determine frequency of suicide-related discussions in routine primary-care encounters with depressed patients along with demographic predictors.
- Identify process variables that may or may not influence the likelihood that suicide will be discussed in primary care.
- Analyse interview style related to enquiring about suicide and responding to patient responses to enquiry as well as unsolicited disclosure.

Key messages

- Suicide is addressed in a small minority of encounters with depressed patients in primary care.
- Suicide is rarely discussed with depressed male patients who are at high risk for suicide.
- Physician enquiries related to suicide are often made with patients who have the lowest levels of ideation, and the enquiries themselves are often biased to elicit a denial of ideation.

Strengths and limitations of this study

- The study involved a large number of primary care physicians and patients representing real-world patient encounters.
- It is unknown if the topic of suicide had been discussed in previous encounters and how such discussion influenced the present encounter.
- We were unable to identify significant predictors of suicide-related discussion, yet we were able to demonstrate that some likely candidates such as participatory decision-making style and trust were not sufficient.

INTRODUCTION

Depression treatment in primary care patients is common in the USA, Europe and worldwide. Unmet need makes it likely that primary care will continue to be the dominant source of depression treatment in years to come. Depression is...
Suicide-related discussions with depressed primary care patients—quality gaps

a robust risk factor for suicide. Suicide is a stigmatised behaviour, accounting for more than 30 000 deaths and more than 300 000 self-harm related emergency department visits per year in the USA. In 2007, the most recent year with available data, suicide was the eighth leading cause of death for US males aged >17, occurring at a rate of 23.3/100 000; for females, it was the 17th leading cause of death occurring at a rate of 5.75/100 000. Despite strong evidence that people who die by suicide are more likely to have seen a primary care provider than a mental-health provider prior to their death, suicide-related discussions in primary care appear to be rare. US adults are more than twice as likely to have seen a primary-care provider (45%) than a mental-health specialist (20%) in the month preceding their death. The frequencies of general practitioner visits in the month prior to suicide in Europe are similar. There is evidence that effective depression treatment in primary care can reduce suicide ideation, particularly in older adults who are at highest risk.

Underdetection and undertreatment of depression in primary care have been a longstanding concern and focus of quality-improvement efforts. The problem is pronounced for men, who are also at more than four times the risk of suicide across the lifespan.

Little is known about the detection of, and response to, suicide risk in depressed primary-care patients. Using standardised patients portraying depression and adjustment disorder, Feldman et al identified several factors that predicted a physician would enquire about suicide including: severity of depressive symptoms, patient initiated request for antidepressant medication, academic practice setting and personal experience with depression on behalf of the physician. Equally important, Feldman et al did not find any significant associations between physician age, gender, type of specialty, perceived barriers to, or confidence in treating depression, or, communication style as measured by the Measure of Patient-Centred Communication. They were left with 57% of the variance attributable to unmeasured physician factors.

Patient centredness, with respect to both communication and environment, has been emphasised as an important process variable related to quality care. We sought to identify additional process variables that might predict the likelihood that suicide would be discussed in routine primary-care visits.

METHODS

This is a secondary analysis of recordings and self reports by physicians and patients participating in The Establishing Focus Study. Conducted between 2002 and 2006, the Establishing Focus study was a randomised controlled trial of a brief intervention to increase physician skills at organising and prioritising encounter time with particular emphasis on using a patient-centred approach. The study was conducted in a large metropolitan city and recruited physicians from two settings, an academic medical centre and a large managed care organisation.

Physicians were randomised to an educational seminar followed by on-site coaching or no-intervention. Physicians completed several questionnaires immediately after each patient encounter (details below). Patients were recruited at the time of appointment, on a sequential basis, for all of the physicians enrolled in the trial. Consenting patients completed questionnaires (details below) prior to their clinic session and agreed to have the encounter audio-recorded. Inclusion criteria ensured that patients had seen the physician at least once prior to the index encounter.

Primary outcomes for the Establishing Focus study included protocol (agenda setting) behaviours demonstrated during the early, middle and late phases of encounters, encounter length, number of concerns raised, patient satisfaction, trust and functional status. All procedures for the original study, as well as the current analysis, were approved by the University of Washington and Group Health Cooperative institutional review board.

PATIENT MEASURES

Patient demographics included gender, age, income and race-ethnicity categorised as White, Black, Mixed and Other. The Patient Health Questionnaire (PHQ9) was used to assess depression symptom severity. Scores greater than 14 were coded as positive for depression. Any response greater than ‘Not at All’ on item 9 was coded as positive for suicide ideation. Patients also reported current pain on a six-point Likert-type scale.

The Medical Outcomes Study Participatory Decision-Making Scale was used to assess differences in patients’ perceptions of their physician’s decision-making style. The Health Care Climate Questionnaire (HCCQ) contains 15 Likert-type items assessing how supportive of their autonomy patients believed their physicians were on the day of the visit.

The trust subscale of the Primary Care Assessment Survey (PCAS) assesses differences in patients’ confidence about their physician’s integrity, competence and willingness to act in their behalf. This subscale contains eight Likert-type items assessing patient trust and has been demonstrated to predict self-reported health improvement. One patient-satisfaction item from the PCAS was also used.

PHYSICIAN MEASURES

Physician measures included gender, whether or not they had been assigned to the original study’s experimental condition and the type of practice environment in which they worked, either a health-maintenance organisation or an academic-affiliated clinic. Physicians rated how fatigued and how rushed they felt during the encounter by two single items, each on seven-point scales.
SESSION CODING
We utilised a qualitative approach to identify adult primary-care encounters in which depression or suicide was discussed. Two research assistants were trained to identify depression and suicide-related discourse. The training included a glossary of depression and suicide-related terms and feedback on a subset of encounters screened by one of the authors (SDV). Raters were instructed to use a very liberal interpretation of depression or suicide discourse, such that any content that appeared to have a psycho-social focus was to be included. All discrepancies between initial ratings were resolved by one of the authors (SDV) in conjunction with the raters. The raters listened to each session and coded it as positive or negative for both depression and suicide content. For each session, they noted the time within the session that the first occurrence of depression/suicide discourse occurred and who initiated it. For positively coded encounters, they transcribed the text segment associated with the positive coding(s).

All transcribed text segments were subjected to discourse analysis, including (1) how the topic of suicide was introduced into conversation, (2) by whom the topic was introduced and (3) the response (or non-response) that followed patient disclosure of suicide ideation. Responses that appeared to follow up on the patient’s disclosure of suicide ideation were coded as engaging. We applied a liberal interpretation to being ‘on topic’, coding responses that were related to the topic of depression or treatment of depression or requests for clarification as being engaging. Responses that appeared to shift topic or reinforce denial of ideation were coded as disengaging.

QUANTITATIVE ANALYSES
We conducted univariate logistic regression analyses to identify potential predictors of depression-related and suicide-related discussions using Stata V.10.36

PARTICIPANTS AND SETTING
Between July 2003 and October 2004, Establishing Focus investigators invited all physicians (n=75) in a convenience sample of 12 community-based primary care clinics serving the Puget Sound region to participate in this study. A total of 59 (79%) physicians consented to participate. Forty-eight physicians participated in all aspects of the study. Thirty-one worked in a university-affiliated primary care network consisting of eight neighbourhood clinics. Seventeen physicians worked in a consumer-governed, non-profit healthcare system (of these, 17 completed all components of the study—three disenrolled).

Patient recruitment began approximately 6 months following completion of the Establishing Focus physician training and lasted 1 year (March 2004 to March 2005). Eligibility criteria included: being 18 years or older, acting as their own legal guardian, having seen the physician at least twice in the previous 2 years, having no serious cognitive impairment and fluency in English. Clinic staff advised study coordinators when eligible patients arrived. The majority (71%) of patients approached agreed to participate. Most (98%) participants completed the study questionnaires following the visit.

RESULTS
The 48 enrolled physicians saw 1776 consenting patients. Of these, 43 physicians saw 128 patients who scored positive for depression. Nearly two-thirds of the depressed sample was female. Only lower levels of pain predicted that a depression discussion would occur, while only female gender predicted that a suicide-related discussion would occur. Depression was discussed in 52% of the encounters. Suicide ideation was endorsed by 59% (n=75) of participants, yet suicide-related discussion occurred in only 11% (n=13) of encounters. Although suicide ideation was endorsed in equal proportions by males and females, suicide was discussed in only one encounter with a depressed male. The overall age range in the sample was 18 to 83, in the depressed group (18 to 76) and in the suicide discussion group (18 to 76). Detailed patient-level demographics are presented in table 1.

Physician gender and practice type predicted the likelihood of discussing depression. No physician variables were associated with discussing suicide (table 1).

Only higher ratings of physician decision-making style were associated with discussing depression, and no process variable predicted suicide-related discussion (table 2).

Categorical endorsement of any suicide ideation versus none on PHQ9 item 9 was equal for men and women; however, men were 5% more likely to endorse suicide ideation greater than ‘several days’ (table 3).

When suicide was discussed, the conversation was more frequently initiated by physicians (n=8) than by patients (n=5). No male patients initiated suicide-related discussion. One female patient raised the issue of suicide ideation in a declaration that she was not feeling suicidal; the other four declared the presence of ideation.

In seven of the eight instances, physicians introduced the topic of suicide by asking explicitly whether the patient wanted to hurt or harm themselves or commit suicide (table 4). In five of the eight questions, physicians used words or phrases that were characterised by linguists as having ‘negative polarity.’ These words and phrases are held to reveal (in their formulations) that
the questioner ‘has grounds for preferring one answer to another—in this case a negative answer’\textsuperscript{37} (see also Borkin\textsuperscript{38} and Heritage\textsuperscript{39}).

Four of the five patients who initiated suicide-related discussion endorsed the presence of suicide ideation, while one explicitly denied it, despite having indicated on her PHQ9 that she was being bothered by thoughts of death or hurting herself more than half the days in the past 2 weeks (table 5).

Physicians responded to disclosure of suicide ideation in equal numbers with respect to engaging-versus-disengaging communication style. Interestingly, they were twice as likely to use an engaging rather than disengaging communication style when the patient denied suicide ideation (box 1).

*Depressed* is indicated by a Patient Health Questionnaire score of >14. ‘Experimental condition’ indicates the physician was a part of the original intervention.

**Statistically significant predictor of discussing depression (p<0.05).**

†Statistically significant predictor of discussing suicide (p<0.05).

‡Two physicians had two encounters in which suicide was discussed; hence only 11 unique physicians for 13 encounters.

### DISCUSSION

Depression continues to be underaddressed in primary care. We found high rates of suicide ideation in this sample of depressed primary-care patients. Consistent with other reports, suicide was rarely discussed. Of note, in the few cases in which physicians asked about suicide, it was with patients who had the lowest levels of suicide ideation as reported on the PHQ9. This raises the question as to why patients with frequent ideation are not being identified. Perhaps most disturbingly, while suicide ideation was equally prevalent in males and females, it was only discussed in one encounter with a male patient.

We know of no research investigating the impact of micro-linguistic interviewing strategies on patient

*Characteristic predicted that a depression-related discussion would occur (p<0.05).
The disclosure of suicide ideation. In a study aimed at eliciting patient concerns, it was demonstrated that even a single word can influence whether patients share all of their concerns in a primary-care encounter. Our findings suggest that when physicians ask about suicidal ideation, they often do so with negative polarity, which may inhibit full disclosure. Furthermore, there may be compounded effects when a question is negatively polarised, and the physician follows up a patient denial in a way that reinforces the negative answer (e.g., ‘that’s good’). Future research on how patients and providers collude to avoid important disclosures about suicide and depression is warranted.

Based on our findings, we recommend that education programmes be designed to teach patients to ‘ask your doctor’ about depression through public-health campaigns and quality-improvement efforts implemented to teach physicians that suicide-related discourse should be part and parcel of addressing depression.

Patient centredness does not guarantee that discussions about suicide will occur in primary-care encounters. Specific methods for increasing suicide-related discourse in primary care are needed.

Training for physicians varies a great deal in the US. Physicians who train with patient populations that carry a high burden of suicide may receive more guidance for engaging patients around suicide, and this may account for physician variance related to how frequently they broach the topic and the style of enquiry used. Educational interventions should be developed and tested to determine the ability to modify these important physician behaviours.

LIMITATIONS
Although this sample is large, the number of identified suicide-related conversations was small, reducing our statistical power to perform inferential analyses. It is possible that the low occurrence of depression and suicide-related conversation is due to the fact that the patient and provider had discussed this topic at previous visits. It is also possible that many patients were being followed by mental-health specialists and addressing suicide risk there. While some physicians may have been aware that the patient in question was being followed in specialty care, a prudent clinical action would include assessing for recent specialty care visits and intent for ongoing management in specialty care—something we did not see. From a clinical risk management perspective, we summarise the template physician phrases initiating suicide discussion in Table 4.

Table 4  Physician phrases initiating suicide discussion

<tr>
<td>1. Since we talked on the phone the other day, I know you’re down, but you’re not, like, thinking of hurting yourself or anything?</td>
<td>No</td>
</tr>
<tr>
<td>1. Sometimes people, when they have thoughts of feeling really sad, they have thoughts of harming themselves. Have you ever had thoughts of suicide or killing yourself?</td>
<td>Mmm-mm (no)</td>
</tr>
<tr>
<td>1. Okay. Do you have thoughts of hurting yourself or anything like that?</td>
<td>No</td>
</tr>
<tr>
<td>1. Okay, well, those are definitely depression symptoms. Do you feel like harming yourself?</td>
<td>Mmm, not really</td>
</tr>
<tr>
<td>1. Have you had any thoughts of hurting yourself?</td>
<td>Yeah</td>
</tr>
<tr>
<td>1. You’re definitely not thinking about hurting yourself or anything like that?</td>
<td>You know, I have to be honest…(patient goes into long description of stressors and attitudes towards suicide, with ultimate denial of intent but clearly has thoughts of wishing she were dead)</td>
</tr>
<tr>
<td>1. Are you suicidal?*</td>
<td>No not yet, I haven’t thought about it</td>
</tr>
<tr>
<td>1. Some people get so down that they are having thoughts about ending your life</td>
<td>No</td>
</tr>
</tbody>
</table>

Italic text indicates negative polarity.

*Denies it to the physician but reports being bothered by thoughts of death or of hurting herself ‘Several days’ in the past 2 weeks on the Patient Health Questionnaire.
Suicide-related discussions with depressed primary care patients—quality gaps

</thead>
<tbody>
<tr>
<td>1. I just feel that I haven’t had any suicidal ideation in a year or so, and it’s been very pervasive in the last month</td>
<td>2</td>
<td>Are you (inaudible) at the sleep lab</td>
</tr>
<tr>
<td>2. I don’t know. I just don’t. know, I just don’t—I’m tired of living like this. I’m so tired of living in pain, I don’t want to. I can’t—you know</td>
<td>3</td>
<td>You just save it up for me</td>
</tr>
<tr>
<td>3. I’ve had suicidal things going on with me</td>
<td>3</td>
<td>Oh, I’m sorry to hear that</td>
</tr>
<tr>
<td>4. I think I should just be buried</td>
<td>0</td>
<td>Mm-hmm. Let’s see.</td>
</tr>
<tr>
<td>5. I’m not thinking of suicide anymore†</td>
<td>2</td>
<td>That’s good</td>
</tr>
</tbody>
</table>

*Item 9 asks, ‘How often in the past 2 weeks have you been bothered by thoughts of death or of hurting yourself?’ Response options are ‘Not at all—3,’ ‘Several days—1,’ ‘More than half the days—2’ or ‘Nearly every day—3.’†Spontaneously denied the presence of suicide ideation but indicated being bothered by thoughts of death or hurting herself ‘more than half the days’ in the past 2 weeks on the Patient Health Questionnaire.

Box 1  Engaging and disengaging physician responses

Physician responses to patient denial of ideation

Engaging
1. Anybody in the family ever had suicidal? Let me look through the family history that I do have. Any family history of depression or anxiety that you’re aware of?
2. Have you been taking your Zoloft?
3. You don’t get that?
4. Okay. Do you get out and get things done that you want to get done?

Disengaging
1. Uh huh. Let’s see. Have we checked your thyroid?
2. I didn’t think so

Physician responses to patient’s endorsement of ideation

Engaging
1. When was the last time?
2. Let me search the (hospital) and see if one of their psychiatrists who has started*
3. Oh, I’m sorry to hear that

Disengaging
1. Are you (inaudible) at the sleep lab?
2. You just save it up for me!
3. Mm-hmm. Let’s see. Shortness of breath

*Patient interrupts physician at this point; he returns to referral after interruption.

Suicide ideation is present in a significant proportion of depressed primary care patients but rarely discussed. Men, who carry the highest risk for suicide, are unlikely to disclose their ideation in the encounter. Perhaps more disturbing is that physicians are unlikely to broach the subject of suicidal ideation with their male patients. Patient disclosure of suicide ideation is an important first step in preventing suicide. Physicians should be encouraged to ask about suicide ideation in their depressed patients, particularly with men, who are at highest risk of dying by suicide.

CONCLUSIONS

Suicide ideation is present in a significant proportion of depressed primary care patients but rarely discussed. Men, who carry the highest risk for suicide, are unlikely to disclose their ideation in the encounter. Perhaps more disturbing is that physicians are unlikely to broach the subject of suicidal ideation with their male patients. Patient disclosure of suicide ideation is an important first step in preventing suicide. Physicians should be encouraged to ask about suicide ideation in their depressed patients, particularly with men, who are at highest risk of dying by suicide.
