AIMS

ABSTRACT

Objectives: To investigate whether life event stress was associated with greater psychological distress and poorer quality of life in older individuals with chronic obstructive pulmonary disease (COPD), in comparison with their counterparts without COPD.

Design: Cross-sectional study.

Participants: A population-based sample (N=497) of individuals aged 65 and above with COPD (postbronchodilatation FEV1/FVC<0.70, N=136) and without COPD (N=277).

Measurements: We measured life event stress, depressive symptoms (GDS, Geriatric Depression Scale), cognitive symptoms and function (CFQ, Cognitive Failures Questionnaire and MMSE, Mini-Mental State Examination), and physical and mental health functional status (SF36-PCS, Physical Health Component Summary and SF36-MCS, Mental Health Component Summary) in participants with and without COPD.

Results: In two-way analysis of variance controlling for potential confounders, life event stress was associated with significant main effects of worse GDS (p<0.001), SF36-PCS (p=0.008) and SF36-MCS scores (p<0.001), and with significant interaction effects on SF36-PCS (p<0.001), SF36-MCS (p=0.034) and MMSE (p=0.02) in participants with and without COPD. The main effect of COPD was found for postbronchodilator FEV1 (p<0.001) and cognitive symptoms (p=0.02).

Conclusions: Our findings indicate that life event stress was associated with more depressive symptoms and worse quality of life in individuals with COPD, much more than in those without COPD. Further studies should explore the role of cognitive appraisal of stress, coping resources and psycho-social support in this relationship.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) stands out among chronic diseases with its high and rising prevalence and mortality,1 poor quality of life, frequent hospitalisation and huge societal burden of care.2 Because patients with COPD bear a heavy burden of psychological disturbance, psychiatric morbidity and disability in daily living activities,3 4 the mental health of COPD patients has received growing attention in recent years.

Life event stress is increasingly recognised to play important roles in the development and outcomes of chronic illness such as type II diabetes, coronary heart disease, gastrointestinal disorders and obstetric outcomes,5 Stress is well known to result in depression, psychological burnout, post-traumatic stress...
disorder (PTSD) in all age groups, as well as cognitive impairment in late life. Among COPD patients, an intrinsic source of stress is directly related to their illness, involving the experience of anxiety and distress provoked by breathing difficulties, including muddled thoughts, heightened emotions, extreme fear and panic and decreased physical energy, and various difficulties in emotional functioning, sleep and rest, physical mobility, social interaction, activities of daily living, recreation, work and finance. However, the impact of life event stress in general, including those extrinsic to illness-related experience on the physical and mental functioning and quality of life of individuals with COPD in comparison with non-COPD individuals, has rarely been investigated. The aim of this study was to investigate whether life event stress was associated with greater psychological distress and poorer quality of life in older individuals with COPD, in comparison with their counterparts without COPD.

The present study analysed data collected on COPD status, life event stress and measures of pulmonary function, cognitive function, depressive symptoms and quality of life in a population-based sample (Singapore Longitudinal Ageing Study) to investigate the effect of life event stress on psychological functioning and quality of life. We hypothesised that life event stress in the whole sample would be associated with depressive symptoms and poor quality of life (main effect), but would have a stronger association among individuals with COPD than among non-COPD individuals (interaction), suggesting a greater detrimental effect on depressive symptoms and quality of life. A secondary relationship analysis in two-way analysis of variance (ANOVA) was the main effect of the COPD status (and its interaction with life event stress) on primary outcomes of pulmonary and cognitive function, based on the known effects of impaired pulmonary and cognitive function in COPD.

METHODS
Study design and participants
The participants in the study were a subsample recruited from one locality (Bukit Merah) in the South Central region of Singapore Longitudinal Ageing Study (SLAS-2), a prospective population-based cohort study of ageing and health of community-dwelling elderly. We interviewed one participant from each household who were Singaporean citizens or permanent residents aged 65 or older who were able to give informed consent. Those who were too frail or ill and unable to complete the interview, for reasons such as from poststroke aphasia, cachexia or profound dementia, were excluded. The participants who completed interviews and provided technically acceptable spirometric data (N=497) represented a response rate of 78.5% of the eligible participants. All participants signed written informed consent for the study that was approved by the National University of Singapore Institutional Review Board.

Chronic obstructive pulmonary disease
We identified cases of COPD among the participants who had characteristic symptoms of COPD and spirometric evidence of chronic airflow obstruction (postbronchial dilatation FEV1/FVC<0.70), in accordance with the definition recommended by the Global Initiative for Chronic Obstructive Lung Disease (GOLD). Questions from the British Medical Research Council Questionnaire on chronic respiratory symptoms were used to elicit symptoms characteristic of COPD: chronic cough and/or sputum lasting at least 3 months in the year and/or breathlessness on exertion.

Ventilatory function testing was performed using a portable, battery-operated, ultrasound transit-time-based spirometer (Easy-One; Model 2001 Diagnostic Spirometer, NDD Medical Technologies, Zurich, Switzerland). Calibration was checked daily with a 3-litre syringe. Forced expiratory manoeuvres were performed with the respondent seated with recommended guidelines and standardisation of procedures: at least three acceptable manoeuvres, with forced vital capacity (FVC) and forced expiratory volume in the first second (FEV1) reproducible within 200 ml. Chronic airflow obstruction as defined as postbronchial dilatation FEV1/FVC<0.70.

Life event stress
Life event stress was measured by an 11-item life events inventory that excluded personal illness experiences directly related to COPD. The participants were asked to indicate yes or no as to whether any of 11 life events had occurred over the past year (‘spouse or partner die, a close friend or family member die or have a serious illness (other than your spouse or partner), major problems with money, a divorce or break up, family member or close friend have a divorce or break up, major conflict with children or grandchildren, major accidents, disasters, muggings, unwanted sexual experiences, robberies, or similar events, a family member or close friend lose their job or retire, physically abused, verbally abused, or pet die’). If the participant indicated (a) life event(s) had occurred, he/she was asked to appraise the event and indicate on a scale of 1 (did not upset me) to 3 (upset me greatly) the extent it upset them. Frequency of life event stress was calculated. The scale also provides a life event stress score appraised by the participant that ranged from 0 to 33 with a higher score indicating a participant experienced a greater number of more stressful events.

Depressive symptoms
The presence of depressive symptoms was determined by a depression screening scale for elderly populations, the 15-item Geriatric Depression Scale (GDS-15) with scores ranging from 0 to 15. The GDS was well suited for the study because it is largely free of the measurement artefact due to overlapping somatic symptoms of physical illness(es) and depression. In validation studies in the local older population, translated versions of...
the GDS-15 have been found to be a valid and reliable screening tool for depression: Cronbach’s α of 0.80, and intra-class coefficients of test–retest reliability of 0.83 and inter-rater reliability of 0.94. Using a GDS cut-off of ≥5, the GDS-15 has a sensitivity of 0.97 and specificity of 0.95 (area under curve of 0.98) for determining major depressive disorder according to DSM-IV criteria. Depressive symptoms defined as such by GDS≥5 is clinically significant, and such cases including ‘subthreshold’ depression, had been shown in the same population to be associated with significantly poorer mental and physical health and functional status, and more healthcare resource utilisation compared to non-cases and were similar to or worse than syndrome threshold cases of depression.18

**Cognitive function**

Cognitive function was measured using the Cognitive Failures Questionnaire (CFQ)19 and the mini-mental state examination (MMSE) which were validated and widely used instruments to assess global cognitive functioning.20 The CFQ uses a five-point Likert-type scale (1=Never, 5=Very often) to evaluate self-reported cognitive problems (eg, ‘Do you need to re-read instructions several times?’). Higher CFQ scores indicate more frequent cognitive problems and higher MMSE scores (0–30) indicate better global cognitive functioning, and MMSE scores of 23 or less are considered to be cognitively impaired.

**Physical and mental functioning**

Physical and mental functional well-being was measured by the Medical Outcomes Study 36-item Short Form (SF-36)21 which has been previously validated for use in Singaporeans.22 Weighted summary measures of Physical Health Component Summary (PCS) score and Mental Health Component Summary (MCS) score were computed with higher scores indicating better physical and mental health functioning and quality of life.

**Statistical analyses**

Data analysis was performed using the software package PASW Statistics (SPSS) V.18. In preliminary univariate analysis, participants with and without COPD were compared with respect to differences in number of life events, and perceived stress score, level of FEV1, CFQ, MMSE, GDS depression, SF-36 PCS and SF-36 MCS scores, as well as potential confounding variables, sex, age, ethnicity, smoking status, number of chronic diseases, using t tests or χ² tests of significance. The independent main effects of life event stress and COPD (independent variables) as well as the interaction effects of life event stress and COPD on measures of pulmonary function, depressive symptoms, cognitive function and quality of life (dependent variables) were analysed using two-way ANOVA using a generalised linear model23 which adjusted for sex, age, ethnicity, smoking status and number of chronic illness. The independent variable of primary interest was life event stress, and the primary outcome variables of interest were depressive symptoms and quality of life. A secondary relationship analysed in the two-way ANOVA model was the main effect of COPD status (and its interaction with life event stress) on primary outcomes of pulmonary and cognitive function. For the outcome variables with significant interaction of life event stress and COPD, the simple effects of their relationships with life event stress score were investigated respectively in participants with and without COPD. Statistical significance was set at p<0.05.

**RESULTS**

This study consisted of 497 participants with the average age of 72.1. Among the respondents, 32.9% had COPD, and 67.1% had no COPD. The proportion of respondents with stressful life events in the past 1 year was 43.4%. The sociodemographic and psychological characteristics of study participants with and without COPD are shown in table 1. Participants with COPD were found to have higher mean age (t=3.328, p=0.001), higher proportion of smokers (χ²=20.586, df=3, p<0.001) and increased number of diseases (t=7.096, p<0.001). No significant difference in the number of life events or perceived stress was observed between COPD and non-COPD participants (p>0.05).

Table 1 shows that compared with those without COPD, participants with COPD had decreased post-bronchodilator FEV1 (t=6.185, p<0.001), MMSE score (t=3.090, p=0.002) and SF-36 PCS (t=2.726, p=0.007) score. There were no differences in CFQ and GDS depression scores between participants with and without COPD (p>0.05) in the whole sample. Next, we evaluated the effect of life event stress on GDS, CFQ, MMSE, SF-36 PCS and SF-36 MCS scores by subgroups of participants with COPD and without COPD. As shown in table 2, two-way ANOVA in general linear model showed significant main effects of life event stress for GDS (F=64.500, df=1, p<0.001), SF-36 PCS (F=7.054, df=1, p=0.008) and SF-36 MCS (F=14.710, df=1, p<0.001) scores, and significant interactions of life event stress with COPD were found as well for GDS (F=10.970, df=1, p=0.001), SF-36 PCS (F=4.055, df=1, p=0.045) and SF-36 MCS (F=4.538, df=1, p=0.034) scores. The simple effects of life event stress on GDS, SF-36 PCS and SF-36 MCS are shown for participants with and without COPD, respectively, in figure 1. Increasing stress score was associated with higher GDS score, lower SF12-PCS and SF12-MCS scores, as well as potential confounders, indicating the association of life event stress with worse psychological distress and poorer quality of life among individuals with COPD, in comparison with non-COPD individuals. The other significant main effect found in two-way ANOVA was of COPD for decreased post-bronchodilator FEV1 (F=17.458, df=1, p<0.001) and higher CFQ scores (F=5.424, df=1, p=0.020) after adjustment of sex, age, ethnicity, smoking status and number of

---

chronic illness, indicating impaired pulmonary and cognitive functions in participants with COPD.

**DISCUSSION**

The principal finding in this study indicated that life event stress was associated with depressive symptoms and poor quality of life in both COPD and non-COPD participants (main effects), but showed a significantly stronger association among individuals with COPD than among non-COPD individuals (interaction), suggesting a disproportionately greater detrimental effect. To our knowledge, no other studies have reported demonstrating this relationship.

It should be noted that participants with COPD actually did not report greater frequency of occurrence or perceived stress score of non-illness-related life events than non-COPD participants. Instead, individuals with COPD appeared to experience the same number of non-illness-related life events and perceived them to be

Adjusted variables: sex, age, ethnicity, smoking status and number of chronic illness.

CFQ, Cognitive Failure Questionnaire; FEV1, Forced Expiratory Volume in the first second; GDS, the Geriatric Depression Scale; MCS, Mental Health Component Summary; MMSE, mini-mental state examination; PCS, Physical Health Component Summary; SF-36, 36-Item Short-Form Healthy Survey.
equally stressful as their non-COPD counterparts, yet showed disproportionately greater psychological distress and poorer quality of life. These results suggest that individuals with COPD may be more vulnerable to the adverse impact of stressful events than non-COPD individuals.

A greater detrimental effect of life event stress on psychological well-being and quality of life in COPD individuals may hypothetically be explained by the possibility that COPD individuals perceive and appraise stressful life events differently to individuals without COPD, or that COPD individuals have poorer coping skills or fewer social and economic resources, or both. We did not have measures of cognitive appraisal, coping resources and social support to explore these hypotheses directly, and this is a limitation of our study.

There are few studies that have investigated the relationship between cognitive appraisal of stressful events, coping strategies and psychological distress in COPD patients. A study by Andrenas and co-investigators have assessed how hospitalised patients with acutely exacerbated COPD appraised and coped with a recent stressful event and their level of psychological distress. They reported that half of the respondents tended to perceive their stressful event as representing a threat, 26% as harmful, 7.6% as a loss, 4.3% as a challenge and 11% characterised the stressful event in some other ways. However, the authors found that neither types of stress-related cognitive appraisal nor number of coping strategies used were significant predictors of COPD-related quality of life than pulmonary function. The present study supports this observation and further indicates that life event stress has a starkly detrimental effect on mental health and quality of life in COPD patients. More studies of the effects of stress management and coping strategy in psychological interventions in COPD should be investigated in randomised controlled clinical trials.

It is increasingly being recognised that the identification of mood and anxiety disorders, and psychological and psychosocial interventions to improve mood and reduce anxiety are important for improving patient-centred outcomes in COPD patients. However, in published clinical guidelines such as NICE, where the initial step care management by practitioners in primary care and general hospital settings includes low-intensity psychosocial interventions for patients with persistent sub-threshold depressive symptoms or mild-to-moderate depression, there appears to be little attention given to identifying stressful life event(s) and supporting COPD patients experiencing stressful life events to prevent the onset of mood and anxiety disorders. In particular, group-based peer support, individual-guided self-help based on cognitive behavioural therapy (CBT) principles

or computerised CBT to reduce patients’ vulnerability to stress may usefully include objective cognitive appraisal of stress, problem-solving coping skills and relaxation therapy to help support COPD patients experiencing stressful life events.

In conclusion, the present study found that life event stress was associated with more depressive symptoms and worse quality of life in individuals with COPD, much more than in those without COPD. Further studies should explore the role of cognitive appraisal of stress, coping resources and psycho-social support in this relationship.
