Knowledge, attitudes and practices regarding infant feeding among HIV-infected pregnant women in Gaborone, Botswana: a cross-sectional survey

Justina Ndubuka, Nnamdi Ndubuka, Ying Li, Caitlin M Marshall, John Ehiri

ABSTRACT

Objectives: To assess knowledge, attitudes and practices regarding infant feeding among HIV-positive pregnant women in Gaborone, Botswana, and factors that influence their infant feeding choices.

Design: A cross-sectional survey.

Methods and study setting: A questionnaire survey of 96 HIV-positive pregnant women attending four public infectious disease control clinics in Gaborone, Botswana.

Results: Only about half of the study participants had knowledge about prevention of mother-to-child transmission (PMTCT) services related to breastfeeding, and very few (19.8%) chose to breastfeed their infants exclusively. Results of multiple logistic regression analysis showed that receiving infant feeding counselling as part of the PMTCT programme was significantly associated with a decision to exclusively breastfeed (OR (95% CI) 5.38 (1.83 to 15.81)). Similarly, HIV-positive pregnant women who received breastfeeding counselling through the PMTCT programme had higher knowledge of PMTCT practices related to appropriate infant feeding (OR (95% CI) 5.91 (1.06 to 34.31)). Women who did not express concern about HIV stigma had significantly higher knowledge of PMTCT practices related to infant feeding (OR (95% CI) 5.91 (1.69 to 15.56)). Knowledge of PMTCT practices related to breastfeeding was negatively associated with the belief that breastfeeding could transmit HIV to the baby (OR (95% CI) 9.73 (3.37 to 28.08)).

Conclusions: Knowledge, attitudes and practices related to breastfeeding among HIV-positive pregnant women need further improvement, and the PMTCT programme should strengthen infant feeding counselling services to assist HIV-positive mothers in making informed and appropriate decisions regarding infant feeding.

INTRODUCTION

Epidemiological data from the Joint United Nations Program on AIDS estimate the prevalence of HIV among adults aged 15–49 years in Botswana to be 23.40%, with more than 160 000 women aged 15–49 years currently living with HIV/AIDS. According to the Republic of Botswana’s Global AIDS Response Report prepared in collaboration with the Botswana National AIDS Coordinating Agency (NACA), the national prevalence of HIV among pregnant women aged 15–49 years is 30.4%, with an estimated 13 072 HIV-infected women giving birth annually. In the absence of interventions to prevent transmission during pregnancy, delivery or breastfeeding for HIV-infected pregnant women, it is estimated that 35% of births will result in mother-to-child transmission (MTCT) of HIV. According to the WHO, if effective interventions are implemented to prevent MTCT (PMTCT), the rate can be reduced to less than 5%.

Owing to the transmissibility of HIV from mother to child, the feeding of HIV-exposed infants remains a significant challenge in controlling the spread of HIV/AIDS. The
dilemma concerning feeding infants of HIV-positive mothers is how to balance the risk of HIV transmission through breastfeeding with the risk of death from causes other than HIV such as pneumonia, diarrhoeal diseases and malnutrition among formula-fed infants. Exclusive breastfeeding (EBF) plays a critical role in the overall health of infants. It is estimated that 3% of all under-5 mortalities in low-income countries could be prevented through optimal breastfeeding during the crucial first year of life. Optimal breastfeeding is considered to be EBF for the first 6 months of life, followed by continued breastfeeding combined with safe and nutritionally adequate complementary feeding up to 24 months of age. EBF is regarded as a global health goal given its strong association with reduced morbidity and mortality, particularly in low-income countries where safe water and sanitation are often lacking.

In 2011, the Government of Botswana (GoB) revised the Botswana National PMTCT guidelines and initiated the use of highly active antiretroviral therapy (HAART) for all HIV-infected pregnant women regardless of their CD4 cell count. The goal was PMTCT of HIV by providing HAART to pregnant women who would otherwise not qualify for treatment, based on their CD4 cell count. For many years, the GoB had recommended that HIV-infected women exclusively formula feed their infants and provide infant formula free of charge until the infant is 1 year of age to support this recommendation. However, in 2011, the Botswana Ministry of Health (MoH) recommended exclusive formula feeding (EFF) for the first 6 months of life only for women for whom formula feeding is acceptable, feasible, affordable, sustainable and safe (AFASS). Botswana has one of the most comprehensive maternal and child health services in sub-Saharan Africa, with nearly 95% of pregnant women receiving prenatal care and having their deliveries attended to by a health professional in a health facility. During prenatal visits, all pregnant women regardless of their HIV status are provided with education and counselling according to the country’s infant and young child-feeding guidelines (based on the WHO 2010 recommendations) to ensure that they make informed and appropriate infant feeding choices. They are also assessed for AFASS using the following criteria: piped water in the house or yard (safety); electricity, gas or paraffin for cooking fuel (feasibility); disclosure of HIV status within 3 weeks after birth (acceptability); having someone in the household employed (affordability and sustainability) and access to a fridge for storage of prepared formula (safety). Depending on the outcome of the AFASS assessment, HIV-infected pregnant women are supported in their decision to either formula feed or breastfeed their infant. For HIV-positive mothers for whom formula feeding is not AFASS, optimal breastfeeding should be recommended and strongly encouraged.

EBF has traditionally been promoted as an important intervention to prevent child morbidity and mortality in low-income countries. In addition to the nutritional value of breast milk for infants during their first months of life, dependence on breast milk not only reduces their exposures to contaminated food and drinks, but also protects them against diarrhoea through the anti-infective properties of breast milk. With the emergence of evidence linking breastfeeding with MTCT of HIV, many women are conflicted on the issue of whether or not to breastfeed their babies. Research evidence has shown that poor-quality counselling in PMTCT programmes and the effects of mass media have created widespread confusion for HIV-infected mothers regarding feeding their infant despite the presence of national guidelines. Women who may be confused by these messages often fail to receive advice to practise EBF, which may result in mixed feeding and an increased risk of HIV transmission. The main objectives of the study were to identify factors that influence infant feeding choices of HIV-infected pregnant women, to provide data for evidence-based decision to improve the quality of Botswana’s PMTCT programme, and to allow the Botswana MoH to assess implementation of the revised guidelines in order to strengthen future efforts. It is hoped that findings from this study will be of value not only to the Botswana AIDS Control Program, but also to other PMTCT programmes in sub-Saharan Africa and other low and middle countries where paediatric HIV/AIDS is a public health challenge.

**METHODS**

A cross-sectional design was used for the study.

**Setting**

The study was conducted in four public infectious disease control clinics (IDCCs) in Gaborone, Botswana, managed by the Gaborone City Council. These clinics were selected because the study population of interest (eligible HIV-infected pregnant women) provides access to universal HAART prophylaxis and thus constitutes a reliable sampling frame from which participants were recruited.

**Study population**

The study population included all HIV-infected pregnant women attending IDCCs in Gaborone for universal HAART programme services during the study period. All HIV-infected pregnant women who presented at any of the four IDCCs during the study period had an equal and independent chance of being included in the study. HIV-infected pregnant women who were Botswana citizens, aged 21 years and above, and willing to participate in the study by providing informed consent were eligible for inclusion. During informed consent, the rationale for the study was explained to potential respondents (in the local language, Setswana) and their voluntary participation was sought. All respondents were informed that their participation was voluntary, and that if they chose not to participate, they would
not lose any benefits from their health facility. They were also informed of their right to withdraw from the study at any time. Women who volunteered to participate in the study were asked to sign the inform consent form. Those who could not read or write were asked to give their thumbprint as a confirmation of their consent. Thus, participation in the study was entirely voluntary and no incentives were provided to respondents. Respondents were assured of confidentiality, and only study unique identification numbers were used on the questionnaires.

Data collection
Data were collected using a structured, interviewer-administered questionnaire. Eligible respondents were interviewed and data were transcribed from their medical records onto the questionnaire. The questionnaire consisted of 35 items that were constructed based on a review of the literature. The questionnaire was translated into the local language (Setswana) and pre-tested on five IDCC attendees who were not involved in the final survey. The questionnaire had the following subsections: sociodemographic information, clinical information, knowledge about PMTCT and infant feeding practices/intentions. Items of the questionnaire elicited information on participants’ sociodemographic characteristics, their knowledge of the objectives of HAART, knowledge of MTCT of HIV, strategies to reduce MTCT of HIV during pregnancy, knowledge of infant feeding practices in the context of HIV, the benefits of EBF, knowledge of the role of mixed feeding (breastfeeding and formula feeding) in MTCT of HIV, access to infant feeding counselling in the context of HAART, infant feeding choices and reasons for the choices, important persons in the decision to breastfeed or formula feed, etc. Data were collected over a period of 4 weeks (11 June–9 July 2012) through interviews administered by an interpreter who was fluent in the local language (Setswana) and received training on ethical conduct of research and data collection.

Data analysis
All questionnaires were entered onto an Excel spreadsheet and checked for accuracy and completeness. The data were then exported to the Statistical Package for Social Sciences (SPSS) V.19 for analysis. With regard to knowledge of PMTCT and PMTCT practices during breastfeeding, we first provided a summary of the number of correct responses by participants and later categorised the responses as either ‘high’ knowledge, when a respondent responded correctly to all of the questions, or ‘low’ knowledge when a participant responded incorrectly to one or more of the questions. Descriptive statistics were used to describe and summarise other variables such as sociodemographic characteristics of respondents, clinical information, knowledge of PMTCT and the important person in decision-making on infant feeding choices. Pearson χ² or Fisher’s exact test was used to compare results between groups. Multiple logistic regression analyses were also employed to control for possible confounding factors and to assess the separate effects of the study variables. ORs with 95% CI were computed to assess factors associated with the choice of breastfeeding, knowledge of PMTCT and PMTCT practices related to breastfeeding. A two-tailed probability level of p<0.05 was chosen as the level of statistical significance.

RESULTS

Characteristics of respondents
Of a total of 102 women from the IDCCs who were eligible for inclusion in the study, 96 volunteered to participate, yielding a response rate of 94.1%. The demographic characteristics of participants, including age, marital status, education, employment status and parity, are shown in table 1. Respondents aged 21–25 years constituted the majority (43.8%; n=42). With regard to marital status, a majority (92.7%, n=89) of the respondents identified themselves as single or cohabiting. Only 7.3% (n=7) had university-level education. Regarding the employment status of the respondents, 39.6% (n=38) were unemployed during the study period. About half of the study participants (53.1%; n=51) had 1–2 children, and 34.4% (n=33) were pregnant for the first time.

All respondents were taking some form of HAART regimen at the time of the study. Table 1 shows that a majority of the respondents (85.4%; n=82) indicated that they received Atripla as their HAART regimen while 6.3% (n=6) received a combination of Combivir and nevirapine (CBV+NVP). As shown in table 1, nearly half of the respondents (55.2%; n=53) identified their husbands/partners as the most influential individual with regard to their choice of infant feeding method. Only 66 of the respondents (70.2%) indicated that they were counselled on infant feeding options recommended for HIV-infected women.

As for knowledge, attitudes and practice (KAP) related to breastfeeding among the respondents, 56.3% of respondents believed that an infant of an HIV-infected mother could become infected with HIV when breastfed, and 88.4% were concerned about AIDS stigma related to HIV and infant feeding choices. Only about half of the respondents had high knowledge about PMTCT and PMTCT-related practices related to breastfeeding. Less than one in five (19.8%) made the decision to exclusively breastfeed their babies (table 1).

Knowledge and practices related to breastfeeding among HIV-infected pregnant women
Data on knowledge and choice of breastfeeding method are presented in table 2. Pearson χ² (or Fisher’s exact test) was used to determine associations between categorical data. Multiple logistic regression analysis was used to assess factors associated with knowledge and choice of infant feeding method. Results indicated that...
receiving infant feeding counselling as part of the PMTCT programme was significantly associated with the decision to exclusively breastfeed (OR (95% CI) 5.38 (1.83 to 15.81)). Receiving infant feeding counselling as part of the PMTCT programme was also significantly associated with high knowledge of PMTCT practices related to breastfeeding (OR (95% CI) 5.91 (1.06 to 34.31)). Women who did not express concern about AIDS stigma had significantly higher knowledge of PMTCT practices related to infant feeding (OR (95% CI) 5.91 (1.69 to 15.56)). Knowledge of PMTCT practices related to breastfeeding was negatively associated with the belief that breastfeeding could transmit HIV to the baby (OR (95% CI) 9.73 (3.37 to 28.08)).

**DISCUSSION**

The basic ethical principle of ‘informed choice’ requires that HIV-positive women are provided with adequate information about their infant feeding options in the context of PMTCT of HIV.17 This study observed that only about half of the HIV-infected women had knowledge of PMTCT and PMTCT practices related to breastfeeding. This finding is similar to that demonstrated by Hailu18 who found that only 30.5% of women in Jimma, Ethiopia had sufficient knowledge of infant feeding options recommended for HIV-positive women.18 Results revealed that counselling on infant feeding provided as part of the PMTCT programme was significantly associated with knowledge of PMTCT practices related to breastfeeding (OR (95% CI) 5.91 (1.06 to 34.31)). Although the Botswana National PMTCT guideline recommends that all pregnant women be counselled on infant feeding choices, only 70% of the respondents indicated that they received such counselling. This suggests that gaps exist within the PMTCT programme guidelines and actual practice.

Continued
Previous studies have explored factors associated with choice of breastfeeding among HIV-infected women. The Botswana Government had promoted EFF by HIV-infected women for many years but presently allows these women to make informed infant feeding choices. 

However, informed decision-making can only take place when the women are provided with individualised, unbiased and accurate information about infant feeding options, and when this information is presented in a way that is compatible with women’s beliefs and at an appropriate health literacy level. This underscores the need for training and retraining of maternal and child health workers in the rationale, principles and methods of infant feeding counselling in the context of HIV infection, based on the WHO and national guidelines on infant feeding in the context of HIV. 

Similarly, providing every pregnant woman with a brief guidance manual on infant feeding in the context of HIV infection written in the local language and with appropriate pictorial explanations might help to ensure that all deserving mothers have access to uniform standard information based on which they can make informed choices about infant feeding.

The Botswana Family Health Survey showed that only 20% of mothers breastfed exclusively for the first 6 months. Similarly, our study found that less than 1 in 5 (19.8%) HIV-infected mothers chose to exclusively breastfeed their babies. This finding is in agreement with those of Tomasoni et al and Hailu who found similar low rates of EBF among HIV-positive mothers (46% and 13.4%, respectively).

Previous studies have explored factors associated with choice of breastfeeding among HIV-infected women. The study by Hailu found that infant feeding choices made by lactating mothers in Ethiopia were significantly associated with their age, while a South African study reported that sociocultural factors (including social stigma of HIV/AIDS, maternal age and family influences on feeding practices, economic circumstances, beliefs about HIV transmission through breast milk and beliefs about the quality of breast milk compared with formula) influenced the decision to exclusively breastfeed. As demonstrated in our study, counselling on infant feeding during antenatal visits was an important predictor of infant feeding choices.

It is noteworthy that women who did not express concern about AIDS stigma had significantly higher knowledge of PMTCT practices related to infant feeding. This may be an indication of the barrier that AIDS-related stigma poses against the uptake of PMTCT services among HIV-infected pregnant women in the study setting. It is known that for social stigma to present a barrier against the uptake of services, affected individuals must accept the devaluation and discredit that accompany the stigma. They must perceive themselves as guilty of moral transgression and accept the blame put on them.

It is important for PMTCT programmes to address stigma in order to promote service uptake. Since many of the key influences on AIDS-related stigma and discrimination are broad based and deeply rooted with the structures of communities, the most effective interventions would be those with sound theoretical foundations and that include attention to individual as well as social and structural barriers. In a review of AIDS-related

stigma in sub-Saharan Africa, Ehiri et al.22 presented the case for a multilevel approach that involves action directed at health workers, religious leaders, members of the judicial system, the media, people living with HIV/AIDS and their family members (table 3).

HIV-infected pregnant women are encouraged to exclusively breastfeed their infants for at least 6 months with proper HAART in high-income and low-income countries owing to the proven benefits of breastfeeding for both the mother and the infant.23 24 For example, the results of a clinical trial in Kenya indicated that giving breastfeeding women a triple-antiretroviral regimen from late pregnancy to 6 months after birth is a safe, feasible way to reduce MTCT in resource-limited settings.25 A cohort study in India found higher rates of HIV-free survival in breastfed infants, reporting a cumulative 12-month mortality of formula-fed infants of 9.6% vs 0.68% among breastfed infants.26 Indeed, the WHO’s recommendation that all mothers who are known to be HIV-infected either on lifelong antiretroviral therapy or not, and who exclusively breastfeed their infants should do so for 6 months, introduce appropriate complementary foods thereafter and continue breastfeeding for the first 12 months of life is based on a plethora of research that demonstrate the positive effect of EBF on HIV-free survival of infants born to HIV-infected mothers.27–32

Evidence shows that there is significant benefit of breastfeeding regardless of the setting as it has been shown to result in positive health outcomes for infants, even in countries with reliable water and sanitation systems, where gastrointestinal problems and other infectious diseases are not a concern.33 34

A majority of the women in this study (80.2%) opted to formula feed their babies. This could be explained by the fact that many healthcare workers commonly prescribe or encourage formula feeding despite the availability of evidence supporting EBF where formula feeding is not AFASS. Doherty et al.34 conducted a series of qualitative interviews of a prospective cohort of 650 HIV-positive mothers in South Africa and considered the influence of healthcare workers on infant feeding choices. The study concluded that health workers possess significant influence over HIV-infected women’s initial infant feeding choices. Doherty et al.34 stated that some women expressed feeling pressured or ‘forced’ by their provider to choose a particular feeding method as a result of their HIV status. Available evidence shows that women who received formula company-produced infant feeding materials from their health providers at

*Adjusted for age and education.
†Adjusted for age.
PMTCT, prevention of mother-to-child transmission.
their first prenatal visit were more likely than those who
did not receive these materials to stop breastfeeding
before hospital discharge and before 2 weeks post-
partum. Those who were uncertain about their decision
to breastfeed, or with a plan to breastfeed for 12 weeks
or less, and who received the commercial materials from
their health providers also had notably lower rates of
EBF and overall duration.35

Thus, understanding ethical considerations and pro-
viding unbiased information about infant feeding
options at the provider level have the potential to
improve outcomes of PMTCT services in Botswana and
similar low-income and middle-income countries where
MTCT of HIV is a public health challenge.

Strengths and limitations

Given the small size of this study, the results provide
only a snapshot assessment of the effectiveness of imple-
mentation of the Botswana PMTCT guidelines of 2011,
which provide HIV-infected pregnant women the oppor-
tunity to make informed infant feeding choices. It is
important to note that only HIV-infected pregnant
women who attended the four study IDCCs during the
period of the study period were recruited. Those who
attended non-participating IDCCs were not interviewed.
These patients might have had different KAP regarding
infant feeding choices from those who were interviewed.
Therefore, the findings from this study cannot be gener-
alised to all HIV-infected pregnant women in the
Botswana National PMTCT programme.

Implications

Paediatric AIDS remains a major contributor to child
mortality in resource-poor countries; thus, interventions
that seek to significantly reduce MTCT of HIV have the
potential to contribute towards achievement of the
Millennium Development Goal of reducing child mortal-
ity by two-thirds by 2015 from the 1990 level.

The finding that a majority of the participants do not
receive the recommended counselling on infant feeding
underscores the need for PMTCT programmes in low-
income countries to take proper care to understand
global and national recommendations on infant feeding
in the context of HIV and to find appropriate ways to
communicate research evidence to HIV-infected women
so that they can make informed choices regarding the
infant feeding option.

The finding that a majority of the respondents in this
study (92.7%, n=89) identified themselves as either
single or cohabiting calls for a need to target this popu-
lation group with interventions to reduce HIV infection
through reduction of risky sexual behaviours.

Further research using qualitative or mixed method
approaches is needed to explore enablers and barriers
in provision of infant feeding counselling recommended
for all HIV-infected pregnant women. Efforts should be
made to understand health workers’ challenges in
implementing this recommendation, and the reasons
why some HIV-infected women do not receive infant
feeding counselling need to be explored. To gather gen-
eralisable information that can be used to improve the
quality of Botswana’s PMTCT programme, it would be
beneficial to replicate this study at other IDCC sites as
well as antenatal care (ANC) clinics in the country. To
effectively improve EBF rates among HIV-infected
women, policymakers must make concerted efforts to
advocate, promote and sustain the universal HAART
programme for pregnant women and strengthen ANC
services. The Botswana MoH should provide adequate
training of healthcare workers on infant feeding coun-
selling for HIV-infected women to ensure that they are
in a good position to provide unbiased and balanced
infant feeding counselling to their clients.

Contributors JN participated in the design of the study, collected data
(interviews of respondents) and prepared the first draft of the manuscript. NN
conducted the literature review and edited drafts of the manuscript. YL
conducted the data analysis and participated in the drafting of the manuscript.
CMH conducted the literature review and participated in the drafting of the
manuscript. JE guided and supervised the conceptualisation and design of
the study, provided oversight of quality control of the research
implementation, and edited drafts of the manuscript.

Funding This research received no specific grant from any funding agency in
the public, commercial or not-for-profit sectors.

Competing interests None.

Patient consent Obtained.

Ethics approval Approval for this study was obtained from the Ethics
Committee of the University of Liverpool, England and from the Botswana
Ministry of Health through the Health Research and Development Committee
(HRDC).

Provenance and peer review Not commissioned; externally peer reviewed.
