Mathematical modelling to restore circulating IGF-1 concentrations in children with Crohn’s disease-induced growth failure: a pharmacokinetic study

A Rao, J F Standing, S Naik, M O Savage, I R Sanderson

ABSTRACT

Objectives: Children with Crohn’s disease grow poorly, and inflammation depresses the response of insulin-like growth factor-1 (IGF-1) to growth hormone. Correcting the inflammation normalises growth velocity; however, removing inflammation cannot be achieved in all children. Our lack of understanding of IGF-1 kinetics has hampered its use, particularly as high IGF-1 concentrations over long periods may predispose to colon cancer. We hypothesised that mathematical modelling of IGF-1 would define dosing regimes that return IGF-1 concentrations into the normal range, without reaching values that risk cancer.

Design: Pharmacokinetic intervention study.

Setting: Tertiary paediatric gastroenterology unit.

Participants: 8 children (M:F; 4:4) entered the study. All completed: 5 South Asian British; 2 White British; 1 African British. Inclusion criteria: Children over 10 years with active Crohn’s disease (C reactive protein >10 mg/l or erythrocyte sedimentation rate >25 mm/h) and height velocity <−2 SD score. Exclusion criteria: closed epiphyses; corticosteroids within 3 months; neoplasia or known hypersensitivity to recombinant human IGF-1 (rhIGF-1).

Interventions: Subcutaneous rhIGF-1 (120 μg/kg) per dose over two admissions: the first as a single dose and the second as twice daily doses over 5 days.

Primary outcome: Significant increase in circulating IGF-1.

Secondary outcomes: Incidence of side effects of IGF-1. A mathematical model of circulating IGF-1 (A_c) was developed to include parameters of endogenous synthesis (K_syn); exogenous uptake (K_a) from the subcutaneous dose (A_s) and IGF-1 clearance: where dA_c/dt=K_syn−K_a×A_s+K_b×A_c.

Results: Subcutaneous IGF-1 increased concentrations, which were maintained on twice daily doses. In covariate analysis, disease activity reduced K_syn (p<0.001). Optimal dosing was derived from least squares regression fitted to a dataset of 384 Crohn’s patients, with model parameters assigned by simulation.

Conclusions: By using age, weight and disease activity scaling in IGF-1 dosing, over 95% of children will have normalised IGF-1 concentrations below +2.5 SDs of the normal population mean, a level not associated with cancer risk.

INTRODUCTION

A quarter of cases of Crohn’s disease now present in children and adolescents under 18 years and its incidence in childhood is increasing. Around one third of the children experience linear growth retardation,
Restoring IGF-1 in children with Crohn’s disease

caused in part by undernutrition and in part by the direct effects of inflammation on growth.4

Growth in childhood is regulated by growth hormone (GH), secreted from the pituitary, which stimulates the production of insulin-like growth factor-1 (IGF-1) by the liver and growth plates of bones.5 Children with active Crohn’s disease have low circulating IGF-1 and increased circulating cytokines.6 7 Treatment of the inflammation, for example, by an enteral diet, results in a reduction in cytokines like IL-6 and an increase in IGF-1 within 3 days.7 Thus, the optimum treatment for improving growth is to eliminate the inflammation. Nevertheless, some children’s inflammation remains intractable to treatment despite the best efforts of clinicians. For this group, there is currently no agreed therapy to enhance growth.

Rats with TNBS-induced colonic inflammation grow poorly8; this is also associated with increased cytokines IL-6 and TNF and a low circulating IGF-1.9 Exogenous IGF-1 given to the rats with colitis enhanced their growth.8 In transgenic mice, without inflammation, high levels of circulating IL-6, generated by a widely acting promoter, depressed both IGF-1 and growth.10 Thus, the link between inflammatory cytokines, IGF-1 and poor growth is strong.11 There is a functional insensitivity to GH in children with Crohn’s disease. Recombinant IGF-1 is now a recognised therapy for children with GH insensitivity syndrome (GHIS) due to genetic defects of the GH receptor or IGF-1 gene;12 we therefore hypothesised that IGF-1 concentrations in children with active Crohn’s disease and poor linear growth could be restored by administering rhIGF-1.

Restoring IGF-1 in children with Crohn’s disease who may have some endogenous production is not straightforward, because high levels of IGF-1 may be harmful. For rhIGF-1 to be therapeutically useful, its circulating levels over the long term should be returned to normal values by replacement, and not given in excess. Patients with acromegaly who have very high concentrations of GH and IGF-1, maintained over decades, have a doubling in the incidence of colon cancer.13 This could, in theory, be compounded in children with Crohn’s disease, as inflammation is also a risk factor for intestinal cancer.

A mathematical model for administration of rhIGF-1, based on detailed pharmacokinetics would resolve these difficulties, as dosing could be tailored to achieve circulating concentrations that remain within the normal range. We therefore undertook a careful study of subcutaneous rhIGF-1 administration in children with Crohn’s disease-induced growth retardation. We developed a model which used physiological parameterisation, disease activity to predict endogenous IGF-1 synthesis and body weight to scale the volume of distribution. Parameters of protein loss, such as protein-losing enteropathy, were also considered. The model was used to recommend dosing which allows children to be treated with rhIGF-1 without its concentration rising above the normal range.

**METHODS**

**Patient selection**

Following ethical approval from the East London & City Research Ethics Committee (reference number 07/H0705/77) and regulatory approval from the UK Medicines and Healthcare products Regulatory Agency (EudraCT number: 2007-004269-16), written informed consent was obtained from the parents and patients attending the paediatric inflammatory bowel disease clinic at Barts and The London Hospital for Children. Inclusion criteria were age ≥10 years; known Crohn’s disease diagnosed by endoscopic, histological and radiological methods;14 a height velocity measured over at least a 6-month period of <-2 SD Score (SDS) according to the patient’s age and gender; and an evidence of active inflammation as demonstrated by either an erythrocyte sedimentation rate (ESR) >25 mm/h and/or a C reactive protein (CRP) >10 mg/l. Exclusion criteria were corticosteroid use in the preceding 3 months; active or suspected neoplasia; known hypersensitivity to exogenous rhIGF-1 (Increlex, Ipsen UK); and the presence of closed epiphyses.

All patients had a full history and physical examination, including an accurate recording of height, weight and assessment of pubertal status. In addition, they also had an ECG and faecal α1-antitrypsin levels (g/l) measured.

**Study design**

Exogenous rhIGF-1 was administered by subcutaneous injection at doses of 120 µg/kg over two admissions. Admission 1 investigated the effects of a single dose of rhIGF-1 over a 24 h inpatient stay. Baseline blood screens included full blood count (FBC), electrolytes, inflammatory markers (CRP and ESR), baseline IGF-1, IGFBP-3, acid labile subunit (ALS) and blood sugar. The Pediatric Crohn’s Disease Activity Index (PCDAI) was calculated.15 16

Each patient was then given a single subcutaneous injection of rhIGF-1 at a dose of 120 µg/kg. Serial venous blood samples were drawn at the following time points: 0, 1, 2, 3, 4, 6, 12, 17 and 24 h. Blood sugars and vital signs were checked regularly. Children ate and drank freely, and continued to receive their prescribed, non-corticosteroid treatment for Crohn’s disease.

Following a wash out of at least 3 months, the participants were readmitted for admission 2, investigating the effects of repeated doses of rhIGF-1. On this occasion, six doses of rhIGF-1 were administered over a 5-day trial period, with doses given at 0, 12, 72, 84, 96 and 108 h. The injection sites were rotated according to the patient’s wishes. Serial blood samples for further IGF-1, IGFBP-3, ALS and blood sugar were collected during the 5 days at 0, 1, 2, 3, 4, 6, 12, 17, 24, 48, 72, 96 and 120 h. Additional samples were also taken for clinical reasons when there was a possibility of hypoglycaemia. If sufficient sample was collected, IGF-1 levels were also measured. In addition, vital signs, FBC, electrolytes and inflammatory markers were measured daily. Patients
were kept as inpatients during the days that the rhIGF-1 was administered, but were allowed home during the 2 days in which they received no injections. Patients were discharged home on day 6.

**Assays and samples**

All samples were stored at −20°C until analysis. Plasma glucose was determined immediately after blood sampling (Beckman Instruments, Palo Alto, California, USA).

IGF-1 and IGFBP-3

IGF-1 and IGFBP-3 levels were measured by competitive binding radioimmunoassay (Esoterix Inc Laboratory Services). The sensitivity of the assay for IGF-1 was 15 ng/ml and the intra-assay coefficient of variation averaged 14.1%. The sensitivity of the assay for IGFBP-3 was 0.3 mg/l and the intra-assay coefficient of variation averaged 13%.

**Acid labile subunit**

ALS levels were measured by radioimmunoassay (ALS-RIA) using purified human ALS as tracer. The intra-assay coefficient of variation ranged from 8% to 17.4%.

**Mathematical model development**

Measured IGF-1 concentrations were fitted for all individuals simultaneously using the non-linear mixed effects modelling software NONMEM V7.1.17 Model building was undertaken using the first-order conditional estimation method with interaction. A turnover model was used according to the following differential equations:

\[
\frac{dA_c}{dt} = K_{\text{syn}} - K_{\text{out}} \times A_c + K_a \times A_a \tag{1}
\]

\[
\frac{dA_a}{dt} = -K_a \times A_a \tag{2}
\]

where \( A_c \) is the amount of circulating IGF-1 at time \( t \); \( A_a \) the amount in the subcutaneous tissue following a dose, with initial conditions adjusted each time a dose is administered; \( K_{\text{syn}} \) a zero order production rate of endogenous IGF-1 in µg/h; \( K_{\text{out}} \) a first-order elimination rate constant in h\(^{-1}\); and \( K_a \) a first order absorption rate constant describing exogenous IGF-1 appearance following a subcutaneous dose in h\(^{-1}\). At steady state prior to exogenous dose, circulating IGF-1 is given by the ratio of \( K_{\text{syn}} \) to \( K_{\text{out}} \).

In addition to \( K_{\text{syn}} \) and \( K_{\text{out}} \), the fixed effect parameters IGF-1 clearance (\( C_L \)) in 1/h and distribution volume (\( V_D \)) in litre were estimated, \( K_{\text{out}} \) being given by the ratio of \( C_L \) to \( V_D \). Variability was tested for all parameters between the participants and residual variability was described using a heteroscedastic model. Allometric weight scaling was applied to \( C_L \) and \( V_D \) a priori using linear scaling for \( V_D \) and weight raised to the power 0.75 for \( C_L \).18 \( K_{\text{syn}} \) was further scaled with linear weight. Tested covariates were CRP, ESR, PCDAI score and age.

Model development used the NONMEM objective function value (OFV); parameter estimate precision was derived through a non-parametric bootstrap and graphical assessment of basic goodness-of-fit plots and model simulations was undertaken. The OFV is proportional to −2 times the log-likelihood of the data given the parameter estimates, and a decrease in OFV of 3.84 with 1 degree of freedom gives a significantly improved fit with a probability p<0.05. A utility function based on the final model was used to predict the average concentration (\( C_{\text{ave}} \)) with a dosing regimen derived from the integral of the IGF-1 against the time curve divided by time. Maximum utility was defined as \( C_{\text{ave}} \) of +0.50 SDS with linear penalty for deviations above and below this target. The dose was optimised to give a model-derived steady-state \( C_{\text{ave}} \) by the following model:

\[
\text{Target} = \text{SDS}_t + \varepsilon_t \tag{3}
\]

\[
\text{Utility} = \sum_{i=1}^{n} (\text{target} - \text{SDS}_t)^2 \tag{4}
\]

where target is the SDS aim (in this case +0.50); \( \text{SDS}_t \) is the individual predicted SDS derived from model predicted \( C_{\text{AVE}} \); and \( \varepsilon_t \) denotes the individual deviations from the target. Utility is minimised \( \varepsilon_t \) by least squares regression.

Demographic details for 384 children aged 8–14 years from the clinical database were each assigned a random PCDAI score (from a uniform distribution 0–48) and also individual model parameters. The utility function was maximised with either fixed dosing, dosing based on weight, weight and age, or weight, age and PCDAI score. Differences in concentrations were explored with 12 and 24 hourly dosing regimens.

**Calculation of sample size**

The size was derived from the number of children needed to show a significant increase in IGF-1, based on the increases in IGF-1 seen in a cohort of children with treated with IGF-1 for GHIS. This showed that in 18 children, the concentration before drug was 330 ng/ml (SEM 20 ng/ml) and the concentration after 4 h was 535 ng/ml (SEM 20 ng/ml). Therefore, to detect a difference in concentration of 205 (535–330) before drug and after 4 h and SD of 84.85 (calculated from SE of the Mean of 20 with sample size of 18), with 80% power at the 5% level of significance, four patients are required.

**RESULTS**

rhIGF-1 therapy in children with Crohn’s disease

Children with active Crohn’s disease and whose growth was inhibited were recruited into the study (table 1). Impairment of height velocity is characteristic of many children with active Crohn’s disease,4 20–22 and all eight participants recruited in the study (median age 12.97) had a height velocity that was more than 2 SDs below
Restoring IGF-1 in children with Crohn’s disease

The severity of disease in any one disease-induced growth failure had depressed circulating IGF-1 concentrations. As previously demonstrated, children with Crohn’s disease is protein-losing enteropathy (PLE) blunted the ability of subcutaneous rhIGF-1 to achieve significant peak concentrations, or if it directly affected IGF binding proteins. PLE was quantified by the concentrations of α1-antitrypsin in stool. Using this measure, PLE had no effect on the change in IGF-1 induced by a subcutaneous injection (figure 2A).

IGFBP-3 concentrations are depressed in children with chronic IGF-1 deficiency and all children in the study had low IGFBP-3 (figure 2B). We wished to determine, however, whether IGFBP-3 concentrations depended on the degree of PLE, as this would indicate that PLE may affect IGF-1 pharmacokinetics. However, no association was observed.

In the second admission, the participants received twice daily doses, to determine if IGF-1 concentrations would be enhanced over a longer period. The initial injection increased the IGF-1 concentrations into the normal range (figure 1A). Increases over a sustained period were successfully achieved (figure 1C) and as expected multiple daily dosing led to lower variability between peak and trough concentrations. Taking the area under the curve divided by time as the average IGF-1 concentration, it became clear that on 120 µg/kg, some children had an average IGF-1 SDS of greater than +2.5, while other children had appropriate concentrations. Increased circulating IGF-1 in acromegaly has been linked with an increased risk of colon cancer. These studies show that the increased cancer risk was seen in individuals whose circulating IGF-1 was +2.5 SDS or greater. Using our data, we developed a model from which the dose–concentration relationship could

**Figure 1A**. Increases over a sustained period were successfully achieved (figure 1C) and as expected multiple daily dosing led to lower variability between peak and trough concentrations. Taking the area under the curve divided by time as the average IGF-1 concentration, it became clear that on 120 µg/kg, some children had an average IGF-1 SDS of greater than +2.5, while other children had appropriate concentrations. Increased circulating IGF-1 in acromegaly has been linked with an increased risk of colon cancer. These studies show that the increased cancer risk was seen in individuals whose circulating IGF-1 was +2.5 SDS or greater. Using our data, we developed a model from which the dose–concentration relationship could
be derived. We then investigated the covariates on which dosing could be individualised. This allowed us to correct circulating IGF-1 without causing excessively high concentrations: ensuring that our dosing regimens resulted in concentrations that were below +2.5 SDS, we developed a utility model to predict the IGF-1 SDS achieved on regular dosing.

**Mathematical modelling of IGF-1 links endogenous production to disease severity**

A turnover model which accounted for both endogenous production and exogenous dosing of IGF-1 was fitted to the data (see methods for mathematical formulae) using non-linear mixed effects analysis. Four fixed effects were estimated, namely endogenous synthesis rate ($K_{\text{SYN}}$), exogenous absorption rate through the skin following subcutaneous injection ($K_a$), systemic clearance ($C_L$) and distribution volume $V_D$. Parameter level random effects (intersubject variability) were included on $K_{\text{SYN}}$ and $C_L$ (table 2). A further level of random effects (interoccasion variability) also provided significantly improved fit when added to $K_{\text{SYN}}$. Following a limited covariate analysis, the PCDAI score was found to significantly improve fit when added to $K_{\text{SYN}}$, with $K_{\text{SYN}}$ falling with increasing disease severity (figure 3A). The effect of disease severity as measured by PCDAI was tested for $C_L$ and $K_{\text{SYN}}$ with significant improvement ($p<0.001$) being shown for $K_{\text{SYN}}$. Furthermore, adding the PCDAI score as a covariate to $K_{\text{SYN}}$ allowed interoccasion variability to be removed without detriment to the model fit (no change in log-likelihood). Adding PCDAI to $K_{\text{SYN}}$ also decreased interindividual variability. In short, disease severity was a major driver of IGF-1 synthesis rate both between patients and in the same patient on different occasions.
There was good agreement between model predictions and observed concentrations (figure 3B), and trendless distribution of standardised residuals, indicating that the parametric modelling assumptions were satisfied (figure 3C–E). The median of the simulated data was not significantly different to the median of the observed data (figure 3F). Superimposing model predictions at a population level and individual level on the observed data showed that model predictions captured the dynamic behaviour of the system (figure 4).

**Dosing to maintain circulating rhIGF-1 concentrations in the target range**

We undertook mathematical modelling to quantify the relationship between endogenous IGF-1 production and exogenous dosing, and to understand how IGF-1 average concentrations (area under the curve/time) can be adjusted. Using the knowledge that in acromegaly there is no increased risk of cancer in patients whose IGF-1 is below +2.5 SDS, we defined the optimal IGF-1 concentration range as being between 0 and +2.0 SDS. This range would improve growth without elevating cancer risk. Different possible dose scaling systems were then explored to maximise the probability of an individual having IGF-1 levels in the target range. By individualising dose by weight, age (because different aged children have different target circulating IGF-1 levels) and PCDAI score, 92.7% of children were predicted to be corrected to less than or equal to +2.0 SDS (95.3% below +2.5 SDS; figure 5). We can therefore suggest a dosing scheme that limits the risk of malignancy to that of the normal patient population. The dosing schedule recommended from the utility function is age 10 to <12 years, 21 µg/kg plus 1 µg/kg /PCDAI point; age 12 to <14 years, 41 µg/kg plus 1.4 µg/kg /PCDAI point.

**DISCUSSION**

Impaired growth has been a recognised feature of children with Crohn’s disease for 50 years. In 1986, low IGF-1 was associated with poor growth in these children; over the following decade, it was realised that the depressed concentration was a direct consequence of inflammation, and not merely the result of poor energy intake or undernutrition. The best strategy to increase IGF-1 and therefore to improve growth is the resolution of inflammation. Treatments which reverse the inflammation, but do not actively suppress growth, were not significantly different to the median of the observed data (figure 3F). Superimposing model predictions at a population level and individual level on the observed data showed that model predictions captured the dynamic behaviour of the system (figure 4).

IIV, interindividual variability; PCDAI, Pediatric Crohn’s Disease Activity Index.
Figure 3  Insulin-like growth factor-1 (IGF-1) in a mathematical model. (A) Increasing disease activity (Pediatric Crohn’s Disease Activity Index) significantly (p<0.001) diminishes the estimates of $K_{syn}$ in the covariate model building. (B) Population model predictions versus observed concentrations are unbiased, indicating good structural model fit. (C) Individual model predicted concentrations are in agreement with observed concentrations. (D) Conditional weighted residuals (CWRES), which are a form of standardised residuals expected to follow the Normal Independent Distribution (NID; 0,1) lie within −2 and +2 SDs and do not change with model predictions, indicating good structural model fit. (E) Similarly, the QQ plot of CWRES indicate that the assumption of normality of residuals is met; (F) Median observed IGF-1 concentrations (solid line) similar to median simulated (dashed line) and observed median lies within 95% CI of the model simulations (grey-shaded area).
such as surgery,\textsuperscript{31} anti-TNF\textsuperscript{32} \textsuperscript{33} and enteral diets\textsuperscript{6} \textsuperscript{34} have all been shown to improve linear growth.

Nevertheless, there are patients with Crohn’s disease whose inflammation cannot be reversed. In this group, we need a distinct strategy to accelerate growth. Both hGH\textsuperscript{35} \textsuperscript{36} and rhIGF-1 have been suggested. As patients with Crohn’s disease have a functional insensitivity to GH, the present study examined the possibility that

\textbf{Figure 4} Population level (blue line) and individual (red line) model predictions are similar to observed data (black open circles) in both (A) single dose and (B) repeated doses in each part of the study.
rhIGF-1 would be efficacious in improving IGF-1 concentrations, as it does in children with GHIS. However, there are significant problems in applying our knowledge of rhIGF-1 usage in GHIS to children with Crohn’s disease. First, children present at a much later age in Crohn’s disease than they do in GHIS, which is caused by a genetic mutation (approximately 8–15 years as opposed to less than 5 years old). The compartments of the IGF-1 system including several IGF binding proteins cannot be assumed to distribute as they do in younger children, particularly if the relative volumes of these compartments change at the time of puberty. Second, both IGF-1 and the IGF binding proteins are circulating proteins. Proteins are lost into the intestine through PLE, where inflammation reduces the ability of the intestinal vasculature to maintain them in the capillary lumen.37–39 The PLE could, in theory, alter the kinetics of IGF-1. Finally, very high and sustained circulating IGF-1 concentrations are associated with an increase in colon cancer in middle aged and older patients with acromegaly. A modelling approach to kinetics and dosing was necessary to avert causing high average IGF-1 concentrations.

The reduction in IGFBP-3 raises the question as to whether giving rhIGF-1 to children with a reduced IGFBP-3 may increase free IGF-1 concentrations. Since we did not have access to an assay for free IGF-1, our data are not totally informative on this issue. However, they will not have risen to unsafe levels from saturating the IGF-1 binding capacity. The concentrations of IGFBP-3 are not greatly depressed in the affected children. Even in the most severe case, the IGFBP-3 is within 2 SDs of normal. In addition, IGF-1 is over 95% bound to IGF binding proteins, with an excess of binding capacity. In general, when analysing pharmacokinetic data, the changes in protein binding do not affect free concentrations, but may affect free fraction. This means that for two individuals with the same total concentration, the free concentration maybe elevated in the one with lower binding protein. However, two individuals with different IGFBP-3 concentrations given rhIGF-1 will not achieve the same total concentrations because as IGF-1 undergoes first-order elimination, higher free concentrations will be more rapidly eliminated due to homeostasis. On analysing our small dataset, IGFBP-3 was not a significant covariate for the volume of distribution in our model. Indeed, our model predicts that the majority of patients will have total concentrations just above the normal range.

Figure 5 Incorporation of a disease activity index into dose calculations allows an accurate prediction of circulating insulin-like growth factor-1 (IGF-1). Utility function results showing the effect of increasing sophistication on dose scaling method. Scaling by weight, age group and Pediatric Crohn’s Disease Activity Index score limits average IGF-1 concentrations in 93% of children to less than +2 SD score (SDs). Solid lines are the target range of 0 to +2 SDs, dashed lines are for reference –2 SDs and +2.5 SDs.
Restoring IGF-1 in children with Crohn’s disease

for dose scaling is also simple with this method. Furthermore, by using a large dataset of hypothetical patients with real Crohn’s Disease demographics, we were able to show how scaling dose by age, weight and PCDAI score could adequately and safely correct IGF-1 (figure 5).

The goodness-of-fit plots (figures 3B–E and f4) show that the model predictions are an unbiased description of the data and simulated data that are not significantly different to the observations (figure 3F). Furthermore, covariate analysis showed that the disease severity (PCDAI score) significantly reduced endogenous synthesis (Ksyn) rather than affecting IGF-1 clearance. Variations in IGF-1 synthesis distinguish patients with Crohn’s disease from children with GHIS.

A possible criticism of using PCDAI to quantify disease in this context is that it includes growth as a marker of inflammation, and it could be suggested that the dependance of Ksyn on PCDAI might be due to the height velocity element of the index. Recently, the determinants of the disease activity index have been separately analysed for predictive value in defined populations of children with Crohn’s disease.43 Linear growth was discovered not to be discriminatory. This report developed a new index, the weighted Pediatric Crohn’s Disease Activity Index (wPCDAI), based on these observations, which does not include growth. We repeated our covariate modelling with wPCDAI and showed that adding it to Ksyn reduced parameter variability and significantly improved model fit, in the same way as the standard PCDAI had. Thus, the relationship between Ksyn and disease activity was due to the objective measures of inflammation and not to the growth component of the PCDAI calculation.

This report focused on the effects of IGF-1. As aforementioned, hGh may also be of benefit on the linear growth of children with Crohn’s disease.36 It was not the purpose of the present study to examine which therapy would be more efficacious; however, future studies comparing IGF-1 with hGH in a controlled randomised multicentre study are planned. This trial will also give us the opportunity to test the dosing regimen derived from this model presented in the present report on a wide sample of children.

Patients and their support groups have long requested more research into therapies that directly improve growth of children with Crohn’s disease. As aforementioned, hGh may also be of benefit on the linear growth of children with Crohn’s disease. However, there are no data in addition to those published except as the individual numerical results that are displayed as figures. Patient identifiable data cannot be shared, as this is a condition of the research ethics committee approval.

Acknowledgements We acknowledge the expertise of the paediatric gastroenterology and research nursing staff at Barts Health NHS Trust in this inpatient study.

Contributors IRS conceived the study and helped in its design; obtained the funding, ethics, MHRA approval and drafted initial manuscript; JFS developed the mathematical modelling; AVR consented the patients; arranged admission and undertook all the investigation; SK oversaw the clinical care of the patients while admitted for research investigation. MOS helped design the study and provided paediatric endocrinology expertise. All authors contributed to the final manuscript.

Funding The work was funded by a project grant from the Crohn’s and Colitis Foundation of America (No. 1774). The IGF-1 was supplied free of charge by Ipsen UK, who also paid for the rhIGF-1 and IGFBP-3 measurements. The study was adopted by the Medicines for Children Research Network (MCRN) of the National Institute of Health Research and accredited by the UK Clinical Research Network (UKCRN). JFS received funding from a UK Medical Research Council Fellowship (grant number G1002305).

Competing interests None.

Ethics approval East London Research Ethics Committee; MHRA.

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement Anonymised original data will be given to research academics at recognised university departments in line with the policies of Queen Mary, University of London. Requests should be made to Professor Sanderson. However, there are no data in addition to those published except as the individual numerical results that are displayed as figures. Patient identifiable data cannot be shared, as this is a condition of the research ethics committee approval.
