The independent associations of recorded crime and perceived safety with physical health in a nationally representative cross-sectional survey of men and women in New Zealand

Gina S Lovasi,1 Charlene E Goh,1 Amber L Pearson,2 Gregory Breetzke3

ABSTRACT

Objectives: We investigated associations of officially recorded crime and perceived neighbourhood safety with physical health, evaluating potential effect modification by gender.

Setting: Nationally representative population-based survey in New Zealand.

Participants: Individual-level data from 6995 New Zealand General Social Survey (2010–2011) participants with complete data on physical health status, perceived neighbourhood safety, sociodemographic characteristics and smoking. Crime rate for each participant’s home census was estimated based on data from the New Zealand Police (2008–2010).

Primary outcome measure: The Transformed Physical Composite Score from the SF-12, a physical health summary score based on self-report ranging from 0 to 100.

Results: We used cluster robust multivariable regression models to examine the associations among neighbourhood crime rates, perceived neighbourhood safety and the physical health summary score. Crime rates predicted adults’ perception that it was unsafe to walk in their neighbourhood at night: for each additional crime per 100 000 residents adults were 1.9% more likely to perceive their neighbourhood as unsafe (95% CI 1.2% to 2.5%). While relatively uncommon, the rate of crime with a weapon strongly predicted perceived safety: for each additional crime per 100 000 residents adults were 1.9% more likely to perceive their neighbourhood as unsafe (95% CI 1.2% to 2.5%). While relatively uncommon, the rate of crime with a weapon strongly predicted perceived safety: for each additional crime per 100 000 residents adults were 1.9% more likely to perceive their neighbourhood as unsafe (95% CI 1.2% to 2.5%).

Conclusion: Gender may modify the associations of officially recorded crime rates with physical health. Perceived neighbourhood safety was independently associated with physical health.

Strengths and limitations of this study

- Use of geographically linked national data.
- Multiple officially recorded crime rates by category using 3 years of data to obtain more stable rates.
- Survey question on perceived neighbourhood safety.
- SF-12 instrument used for outcome assessment has been validated and recommended as a population health measure.
- Power to test for interaction by gender on the association between neighbourhood crime and health.
- Cross-sectional and observational study designs limit our ability to eliminate non-causal explanations.
- Physical health status was self-reported, which could result in misclassification.
- Physical health status and crime rates have been shown to have worse physical health,4 5 even after controlling for the potential confounding effect of

INTRODUCTION

Neighbourhood characteristics have previously been shown to influence health.1–3 Crime is one such neighbourhood characteristic. Residents living in areas with higher crime rate have been shown to have worse physical health,4 5 even after controlling for the potential confounding effect of
sociodemographic characteristics. There are several causal pathways by which local crime rates can affect health, including trauma resulting from victimisation or chronic stress and anxiety related to a perceived threat. Stress pathways could involve mental health, sleep duration or stress-coping behaviours such as tobacco use or alcohol intake. Other behavioural pathways could also play a role if outdoor physical activities, such as walking in the neighbourhood, were restricted to minimise victimisation risk, adversely affecting physical health. Thus, potential health benefits may be among the reasons to pursue local crime prevention.

Although recorded crime may be thought to influence health status through perceived safety, the role of perceived safety as a mediator of this relationship has often been assumed rather than tested empirically. Independent or divergent associations have been observed for officially recorded crime as compared with perceived safety problems in analyses predicting health and health behaviours, suggesting that recorded crime and perceived safety may not be simply serving as proxies for each other. In addition to officially recorded crime, the perception of safety may be influenced by environmental- and neighbourhood-level factors, such as social cohesion, street lighting and neighbourhood physical disorder. A recent systematic review highlighted many inconsistencies in the literature on the link between officially recorded crime and perceived safety with physical activity. Yet, individual perceptions and responses to the local environment may not be the same for all groups. Associations of local crime rates with health have been shown to vary based on local or national socioeconomic context, as well as by gender. Men and women have been shown to differ in their perceived risk of victimisation and fear depending on the type of crime; they have also been observed to vary in their likelihood of exercise associated with perceived safety. It has also been suggested that women might be more exposed to their local area than men, which may contribute to the differences in associations with officially recorded crime and self-reported perception of safety on health.

This study sought to assess the association of officially recorded crime and self-reported perception of safety on physical health status in a national sample of adult New Zealanders using data from the New Zealand General Social Survey (NZGSS) and crime data obtained from the New Zealand Police. The New Zealand General Social Survey is a nationally representative cross-sectional survey of New Zealand residents aged 15 years and over. Detailed information on sampling and methodology of the NZGSS has been previously published. The survey employed a multistage sample, and a total of 8550 participants answered the NZGSS personal questionnaire during a 12-month period from April 2010 to March 2011 (81% response rate). The NZGSS was interviewer administered in person using computer-assisted personal interviews which covered a wide range of social and economic topics, including sociodemographic characteristics, perceived neighbourhood safety and self-reported health.

**MATERIALS AND METHODS**

**Study design and population**

The NZGSS was designed to provide information on the well-being of New Zealanders. The NZGSS is a nationally representative cross-sectional survey of New Zealand residents aged 15 years and over. Detailed information on sampling and methodology of the NZGSS has been previously published. The NZGSS was interviewer administered in person using computer-assisted personal interviews which covered a wide range of social and economic topics, including sociodemographic characteristics, perceived neighbourhood safety and self-reported health.

**Physical health status outcome based on self-report**

The outcome variable of interest—physical health status—was self-assessed and measured in the NZGSS by the commonly used SF-12 Health Index, a short version of the SF-36. The SF-12 consists of 12 questions, covering aspects of physical and mental health. Example questions: “In general, would you say your health is excellent, very good, good, fair or poor?”, “During the past four weeks, how much of the time were you limited in the kind of work or other regular daily activities you do as a result of your physical health?” Responses were weighted and combined into a physical health summary score, the Transformed Physical Composite Score (TPCS) ranging from 0 to 100.

**Officially recorded crime rates**

Data of officially recorded crime throughout New Zealand for the period (2008–2010) were obtained from the New Zealand Police. Crime rates from 2008 to 2010 were selected for their temporal correspondence with the data collection in 2010–2011 characterising a period largely preceding our outcome measurement and using 3 years of data to obtain more stable rates. The data included over 360 000 incidents of crime recorded nationally, which have been geocoded and aggregated from the meshblock level to the census area unit (CAU). Each CAU contains approximately 2000 people. Crime data were categorised by type (violent, property, dishonesty or drug and antisocial), whether a weapon was involved, and whether the offence occurred at night (defined as between 20:00 and 7:59). For
overall crime and each category, the average count over the 3-year period was combined with CAU population data to create average annual rates per 100 000 population (see table 1). Crime rates were then linked to individual data from the NZGSS based on the CAU corresponding to the residential address provided at the time of the NZGSS survey.

**Perceptions of neighbourhood as unsafe at night**

Perceptions of the neighbourhood as being ‘unsafe’ at night was assessed by asking NZGSS participants: “How safe do you feel walking alone at night in your neighbourhood?” Potential answers ranged on a Likert-type 4-point scale from 1 ‘very safe’ to 4 ‘very unsafe’. Responses were dichotomised such that feeling ‘unsafe/very unsafe’ was considered as representing a perceived safety problem for analyses. Similar measures have been used in previous studies either as an individual measure or as part of a composite scale.12 28–30

**Individual sociodemographic characteristics and smoking**

Age group (age 15–24, 25–44, 45–64 and 65+ years), gender, ethnicity (Māori, the indigenous population of New Zealand (1) vs Non-Māori (0)), individual-level socio-economic status (SES), country of birth and smoking status (never, former and current) were considered as physical health determinants that are also potentially associated with place of residence but not on the causal pathway, and thus as potential confounders. SES is a well-known confounder of the relationship between neighbourhood characteristics and health3; available SES measures included education (none or national certificate 1–4, diploma or bachelors or masters or doctorate), employment (currently working for pay (1) vs otherwise (0)), and income ($NZ0–$NZ20 000, $NZ20 001–$NZ40 000, $NZ40 001–$NZ60 000, >$NZ60 000 per year). Being foreign-born has been found to be associated with neighbourhood of residence and physical health status.31 Place of birth was dichotomised into New Zealand-born (1) and born outside of New Zealand (0).

**Statistical analyses**

A linear probability model with cluster robust SEs was used to explore the relationships between crime rates and perception of the neighbourhood as unsafe. Cluster robust linear regression analyses were used to examine the associations between officially reported crime rates and perception of the neighbourhood as unsafe predicting physical health status. An intraclass correlation coefficient (ICC) was used to assess, and cluster robust SEs were used to account for, the potential non-independence of physical health status scores within the same CAU. Due to the correlations between the different types of crime rates (see table 1), we assessed associations for each recorded crime rate separately and did not mutually adjust for multiple categories of crime in the same model. All models controlled for age, gender, ethnicity, place of birth, education, employment, income and smoking status.

Perception of safety was added to models with officially recorded crime rates to test for independent associations with health and to check for patterns of association consistent with mediation of the crime rate-health associations. Mediation was expected to manifest as (1) an association between higher crime rate and lower perceived safety, (2) an association between lower perceived safety and worse health status and (3) attenuation of the crime rate-health association when perceived safety is added to the model. Furthermore, as gender was of interest as a potential effect measure modifier, gender stratification was considered for all analyses; Wald p values to evaluate the statistical significance of observed effect modification were calculated from models including a gender interaction. Participants with missing values for any of the analysis variables (N=1555) were excluded from descriptive statistics and regression

Mean annual rate of crime was calculated for 2008–2010 using count per 100 000 residents for each census area unit; descriptive statistics and Pearson’s correlations shown are calculated across individual NZGSS participants (N=6995).

*The rate of crime with a weapon had a 90th centile of 0.3.

NZGSS, New Zealand General Social Survey.
analyses. Compared to the full sample, participants in our analyses were somewhat more likely to be men, young, educated or employed. All statistical analyses were carried out in a secure data lab in Wellington, New Zealand using Stata V.11.0 software (Stata Corp, College Station, Texas, USA).

RESULTS
Study participants
Table 2 shows the characteristics of the study population (N=6995). There were similar numbers of men (n=3310) and women (n=3685). Twelve per cent of the study participants were of Māori ethnicity. Most participants were New Zealand-born (77%) and 65% of participants were currently employed. Approximately 21% of men reported feeling unsafe or very unsafe walking alone at night in their neighbourhood compared with 52% of women. The physical health index (TPCS based on SF-12) had a theoretical range from 0 to 100, with higher values indicating better physical health. The observed mean and SD were similar for men and women. The ICC for the physical health index across CAUs suggests that 3.1% of the outcome variation may be explained at the CAU level (95% CI 1.7% to 4.5%).

Association between officially recorded crime rates and perceived safety
Total crime rate was significantly associated with the perception of one’s neighbourhood as unsafe for walking at night (table 3). Associations were statistically significant for both genders and for all four types of crimes, except that among men the trend was not statistically significant for dishonesty crime (gender interaction p value=0.03). While relatively uncommon, the rate of crime with a weapon predicted perceived safety: for each additional crime per 100 000 residents in this category women were 15.7% more likely to perceive their neighbourhood as unsafe and men were 10% more likely to perceive their neighbourhood as unsafe.

Association between officially recorded crime and physical health status
Total crime rate had a non-significant association with overall lower physical health among men (table 4). However, among women, the total crime rate, violent crime rate, and crime at night were significantly

TPCS, Transformed Physical Composite Score.
associated with a lower physical health index (coefficients were −0.15, −0.32 and −0.29, respectively). This suggests that for each additional crime per 100 000 residents we would expect a decrease in the physical health index of 0.15 units, or perhaps an approximately 0.3 unit decrease if the additional crime were violent or committed at night. The effect modification by gender was only statistically significant for crime at night (p=0.01).

To assess whether the perception of one’s neighbourhood as being unsafe mediated the associations between recorded crime and physical health status, an indicator of perceived safety was added to models of recorded crime and health status. The addition of perceived safety changed the magnitude of the statistically significant regression coefficients by 8–28% (see table 4). For women, the rates of violent crime and crime occurring at night remained significantly associated with physical health after controlling for perception of neighbourhood as unsafe.

### DISCUSSION

For this population of adults living in New Zealand, we observed robust associations between objectively
recorded crime rates and perceived neighbourhood safety, and between perceived neighbourhood safety and physical health. However, there was some evidence of effect modification by gender in the association between objectively recorded crime rates and physical health. Moreover, the category of crime rates most strongly associated with perceived safety (crime with a weapon) was not among the categories most strongly associated with physical health (violent crime and crime at night). The observed patterns were somewhat supportive of the hypothesised role of perceived safety as a mediator between officially recorded crime rates and physical health among women. However, the observed patterns indicate potential heterogeneity by crime type and gender.

An understanding of the several causal pathways through which crime may affect health can help explain these separate associations, and differences across categories of crime. It appears that for women, violent crime and crimes occurring at night were negatively associated with health status even after controlling for any indirect association through perceived safety. Yet, the magnitude of association between perceived neighbourhood safety and physical health showed a trend to be larger for men than women. These findings highlight separate associations of officially recorded crime versus perceived safety hazards on health, and that these associations may differ by gender. Our results corroborate other studies\(^{12,14,32}\) that have found independent associations for between the perception of safety and officially recorded crime with health status or health-related behaviour.\(^{11,14}\) Perceived safety—instead of merely being a reflection of recorded crime—is an independent construct that can be influenced by a variety of environmental cues such as the physical features of public spaces, lighting levels, media stories and social incivilities.\(^{9}\)

Future longitudinal research should consider how short-term fluctuations and long-term trends in crime rates and other neighbourhood shifts alter individuals’ reported perceptions of neighbourhood safety. While perceived safety may, in part, mediate the association between recorded crime and physical health status among women in our study, the association of perceived crime with adverse physical health was notable and statistically significant among men, even though recorded crime rates were not associated with physical health for these same men.

It is worth noting that when effect modification by gender has been explored in previous studies of crime or safety as predictors of physical health, the patterns have not always been consistent with our findings. For example, others have reported a stronger association between perceived safety and health status for women,\(^{19}\) whereas in this study we found a trend in the opposite direction, though the effect modification was not statistically significant. Some of the literature on perceived safety and physical activity has pointed to stronger associations for men\(^{33}\) or failed to detect an association among women.\(^{16,34,35}\) One potential explanation for the stronger associations between perceived safety and physical activity among men involve reverse causation, with physically healthy men more likely to perceive themselves as being safe from crime. The inconsistent evidence for the association of perceived crime on health status by gender underscores the importance of using officially recorded and perceived crime measures and presenting gender stratified results even when the pattern of effect modification seems contrary to current assumptions.

Coefficients and 95% CIs from cluster robust linear models predicting the physical health index are shown, and coefficients can be interpreted as the predicted difference in physical health status (as measured by the SF-12 transformed physical component score) for comparing those reporting their neighbourhood as unsafe for walking at night versus safe for walking at night; covariates include age, ethnicity, place of birth, education, employment, income and smoking status; crime rates were added one at a time to adjusted models and the coefficients for perceiving neighbourhood as unsafe are shown before and after adjustment for each of these crime rates; italic face is used to indicate statistical significance (p<0.05).
However, the cross-sectional and observational study designs limit our ability to eliminate non-causal explanations such as reverse causation and unmeasured confounding. Physical health status was self-reported and this could result in misclassification. Missing data were also an important limitation. In particular, the large number of participants who selected ‘Not applicable’, ‘Don’t know’ or ‘Refused’ in response to the question on perceived safety (N=1092) may have included those who already avoided walking home at night due to safety concerns or health limitations, and this could lead to a biased estimate of the associations among crime rates, perceived safety and health status. Misclassification or reasons for missing data could also differ by gender, potentially distorting the observed pattern of effect modification. The measure of perceived safety too did not explicitly state the source for concern with safety and some participants may be considering factors such as traffic hazards instead of crime. Last, crime rates in New Zealand are lower than in many other countries (eg, in 2000, the New Zealand violent crime rates were 132.6 per 100 000 compared to 506.1 per 100 000 population in the USA\(^2\); this and other unique sociocultural factors may change how its neighbourhoods function and influence health, limiting the generalisability of our results.

CONCLUSION

In conclusion, complex patterns of association were observed linking crime rates to physical health among men and women in New Zealand. Future studies should continue to explore differences by crime category and by gender, and across the multiple pathways that may link crime rates to physical health status. Usage of officially recorded crime and perceived safety measures is important to tease apart the differences in what they reflect and how they may influence health differently for men and women. Perceived neighbourhood safety in particular appears to be a robust predictor of physical health independent of officially recorded crime rates, and potentially modifiable neighbourhood characteristics affecting perceived safety warrant further investigation.

Acknowledgements The authors would like to acknowledge the support of New Zealand Police who provided crime data for this work; and to Statistics New Zealand who provided access to data from the General Social Survey.

Contributors All authors critically reviewed manuscript drafts and approved the submission. GSL, ALP and GB conceived the project. GB prepared the official crime rate data for linkage to the New Zealand General Social Survey (NZGSS). ALP conducted analyses in the secure data lab, with syntax and input from GSL. CEG created tables from the output files and drafted the initial manuscript. GSL revised and integrated comments on the final tables and text.

Funding The Christchurch City Council initiated the research and the Ministry of Justice Crime Prevention Unit was responsible the provision of funding, which allowed the project to start smoothly. The National Institute for Child Health and Human Development (K01HD067390) provided financial support for the first author.

Disclaimer Access to the data used in this study was provided by Statistics New Zealand under conditions designed to uphold the security and confidentiality provisions of the Statistics Act 1975. The results presented in this study are the work of the authors, not Statistics New Zealand.

Competing interests None.

Ethics approval The linkage and statistical analyses of microdata for this manuscript took place at a Statistics New Zealand Data Lab in Wellington, NZ, and the proposal to do so was approved by the New Zealand Police and Statistics New Zealand.

Provenance and peer review Not commissioned; externally peer reviewed.
