Clinical significance of low forced expiratory flow between 25% and 75% of vital capacity following treated pulmonary tuberculosis: a cross-sectional study

Eric Walter Pefura-Yone,1,2 Andre Pascal Kengne,3 Pierre Eugene Tagne-Kamdem,1 Emmanuel Afane-Ze1,2

ABSTRACT

Objectives: The aim of this study was to assess the prevalence and determinants of post-tuberculosis chronic respiratory signs, as well as the clinical impact of a low forced expiratory flow between 25% and 75% (FEF25–75%) in a group of individuals previously treated successfully for pulmonary tuberculosis.

Design: This was a cross-sectional study involving individuals in their post-tuberculosis treatment period.

Setting: This study was carried out in the tuberculosis diagnosis and treatment centre at Yaounde Jamot Hospital, which serves as a referral centre for tuberculosis and respiratory diseases for the capital city of Cameroon (Yaounde) and surrounding areas.

Participants: All consecutive patients in their post-tuberculosis treatment period were consecutively enrolled between November 2012 and April 2013.

Results: Of the 177 patients included, 101 (57.1%) were men, whose median age (25th-75th centiles) was 32 (24–45.5) years. At least one chronic respiratory sign was present in 110 (62.1%) participants and DAO was found in 67 (62.9%). Independent determinants of persisting respiratory signs were the duration of symptoms prior to tuberculosis diagnosis higher than 12 weeks (adjusted OR 2.91; 95% CI 1.12 to 7.60, p=0.029) and presence of DAO (2.22; 1.13 to 4.38, p=0.021).

Conclusions: FEF25–75%<65% is useful for the assessment and diagnosis of post-tuberculous DAO. Mass education targeting early diagnosis of pulmonary tuberculosis can potentially reduce the prevalence of post-tuberculosis respiratory signs and distal airflow obstruction.

INTRODUCTION

Pulmonary tuberculosis, the most common form of tuberculosis, is an important public health challenge worldwide. The clinical presentation of pulmonary tuberculosis usually combines general signs with chronic respiratory signs including cough and expectoration. The presence of dyspnoea during pulmonary tuberculosis usually indicates the extensive nature of the pulmonary lesions. Radiographic and functional sequelae are very frequent following tuberculosis treatment, and ad-integrum restitution of the lungs is rather less frequent. While functional sequelae are mostly due to restrictive or mixed functional disorders, post-tuberculosis airflow obstruction is also present in an important number of patients. The prevalence of post-tuberculosis airflow obstruction ranges between 5% and 30% across published studies. Furthermore, pathophysiological studies suggest that lesions affecting exclusively the distal respiratory pathways are possible during pulmonary tuberculosis.
We are not aware of published studies on post-tuberculosis distal airflow obstruction (DAO) and the possible connection with persistence of respiratory signs following treatment for pulmonary tuberculosis. The assessment of DAO in routine practice is still a challenge with regard to the indices to be used; however, many have suggested mean median expiratory flow or forced expiratory flow between 25% and 75% (FEF25-75%) to be useful for this purpose. The wide variability of this index limits the possibility of defining a reliable optimal threshold for diagnosing DAO.16 Thresholds of 65% or 60% have been applied in children to characterise distal airflow obstruction.17 18 The aim of this study was to determine the prevalence and factors associated with post-tuberculosis chronic respiratory signs, and to assess the clinical impact of a low FEF25-75% in a group of patients successfully treated for pulmonary tuberculosis.

MATERIALS AND METHODS

Study setting and participants

This study was conducted in the Centre for Diagnosis and Treatment of tuberculosis (CDT) of the Yaounde Jamot Hospital (YJH) between November 2012 and April 2013 (6 months duration). This centre has been described in detail previously.19 20 In short, YJH is the reference centre for tuberculosis and chest diseases for the capital city of Cameroon (Yaounde) and surrounding areas. Over the past 5 years, the centre has diagnosed and treated an average of 1600–1800 patients with tuberculosis every year.

All patients aged 18 years and above, successfully treated for bacteriologically proven pulmonary tuberculosis (new case or retreatment), were invited to take part in the study. Bacteriological proofs of pulmonary tuberculosis were based on the presence of acid-fast bacillary (AFB) on at least one direct sputum smear examination,21 or a positive sputum culture for Mycobacterium tuberculosis. Sputum culture and drugs susceptibility test (DST) were performed for all retreatment cases. Patients with any of the following conditions were excluded: patients with treatment failure, patients with resistance to at least one antituberculosis drug, ongoing bacterial pneumonia or within the 4 weeks preceding inclusion, chronic respiratory condition before TB diagnosis, ongoing treatment with β-blockers, physical or mental inability to perform the spirometry test.

Pulmonary tuberculosis treatment

Tuberculosis treatment at the CDT follows the guidelines of the Cameroon National Tuberculosis Control Programme (NTCP) and the WHO recommendations.22 23 Antituberculosis drugs are dispensed free of charge, and treatment regimens used are standard regimens of category I for new patients and of category II for retreatment cases. New cases are treated with a regimen that includes an intensive phase of 2 months duration with rifampicin (R), isoniazid (H), ethambutol (E) and pyrazinamide (Z), followed by a 4-month continuation phase with rifampicin and isoniazid (2RHEZ/4RH). During retreatment, category I medications (R, H, E, Z) are completed with streptomycin (S). Therefore, retreatment cases are treated with RHEZS for 2 months, followed by 1 month on RHEZ and 5 months on RHEZS (1RHEZ/5RHE). During the intensive phase, adherence is directly monitored by the healthcare team for patients admitted, and during weekly drug collection in those treated as outpatients. The continuation phase is conducted on the outpatient basis and adherence assessed during monthly visits for scripts renewal and drugs collection.

Monitoring and outcomes of pulmonary tuberculosis treatment

During treatment, sputum smear positive patients are re-examined for AFB at the end of months 2, 5 and 6 for new cases, and at the end of months 3, 5 and 8 for retreated patients. At the end of the treatment, patients are ranked into mutually exclusive categories22 23 as: (1) cured—patient with a negative smear at the last month of treatment and atleast one of the preceding; (2) treatment completed—patient who has completed the treatment and for whom the smear result at the end of the last month is not available; (3) failure—patient with a positive smear at the 5th month or later during treatment; (4) death—death from any cause during treatment; (5) defaulter—patient whose treatment has been interrupted for atleast two consecutive months and (6) transfer—patient transferred to complete his treatment in another centre and whose treatment outcome is unknown.

PROCEDURES

Baseline data collection

In this cross-sectional study, baseline data were collected on sociodemographic, clinical, radiological and biological characteristics of patients. Sociodemographic data collected included age, sex, residence (urban vs rural) and formal level of education. The medical history data included current or former smoking (yes vs no), history of tuberculosis and comorbidities (diabetes mellitus). Clinical details included: duration of symptoms prior to tuberculosis diagnosis, persistent of respiratory symptoms (cough, expectoration, dyspnoea). Patients whose symptoms continued at the end of TB treatment were considered as having persistent respiratory symptoms. Radiographic data were collected on the extension of lungs involvement (number of fields affected), the type of lung lesions (cavities, fibrotic lesions), the presence of pleural effusion and mediastinal or hilar lymph nodes. Biological data included the results of the HIV test result. The study was approved by the administrative authorities of the YJH and institutional review board of the Faculty of Medicine and Biomedical Sciences of the University of Yaounde I.
Ventilatory variables measurement

Spirometric measurements were performed in the month following the completion of TB treatment. They were acquired with a digital turbine pneumotachograph (Spiro USB, Care fusion, Yorba Linda, California USA) following the 1994 American Thoracic Society (ATS) standards. All the pulmonary volumes and flow rates were automatically corrected for body temperature and pressure saturated. Measurements were performed under the direct supervision of an experienced pneumologist who is also certified in lung function testing (EWP-Y). The different respiratory indices were measured without bronchodilators and included: forced vital capacity (FVC), forced expiratory volume during the first second (FEV1), forced expiratory flow between 25% and 75% of vital capacity (FEF25–75%) and the ratio FEV1/FVC. The acceptability and reproducibility criteria recommended by the ATS and European Respiratory Society (ERS) guidelines (ATS/ERS guidelines) were respected. At least three manoeuvres up to a maximum of eight were performed as required to obtain the flow rate curve (FVC curve). A 1 min resting period was observed between consecutive manoeuvres. Satisfactory exhalation was considered in the presence of any of the following: (1) no change in exhaled volume (plateau on the volume-time curve) for 1 s after an exhalation time of at least 6 s; (2) the presence of a reasonable duration or plateau in the volume–time curve; (3) inability of the subject to continue to exhale. The largest values for FEV1 and FVC from three acceptable manoeuvres were retained. The authorised difference between the largest values of FVC or FEV1 of the three acceptable manoeuvres was inferior or equal to 0.150 L or 5%. The manoeuvre with the largest sum of three acceptable manoeuvres was inferior or equal to FEV1/FVC. The acceptability and reproducibility criteria count (percentages) and quantitative variables as mean Data were analysed with the use of SPSS V.17 for statistical analysis.

RESULTS

General characteristics of the study population and prevalence of chronic respiratory signs

A total of 189 patients were invited to take part in the study. One refused to consent, 10 had incorrect spirometry records (not acceptable and/or not reproducible manoeuvres) while one had an FEV1/FVC <0.70. Of the 177 participants included, 101 (57.1%) were men, whose median age (25th–75th centile) was 32 (24–45.5) years. Thirty-five (19.8%) patients were current or ex-smokers, 23 (13%) had a prior history of pulmonary tuberculosis and 47 (26.6%) had coincident HIV infection. At least one chronic respiratory sign (CRS) was found in 110 (62.1%) patients at the completion of the antituberculosis treatment. Furthermore, 87 (49.2%), 62 (35%) and 99 (55.9%) patients had persisting cough, expectoration and dyspnoea, respectively, at treatment completion (table 1 and figure 1).

Relationship between FEF25–75% and chronic respiratory signs

Table 2 shows the distribution of chronic respiratory signs at treatment completion, according to FEF25–75% categories. Seventy-five patients (42.4%) had normal FEF25–75%, 35 (19.8%) had intermediate FEF25–75%, while 67 (37.9%) had low FEF25–75%. Persisting cough, expectoration and dyspnoea were significantly more frequent among patients with low FEF25–75%.

STATISTICAL ANALYSIS

Data were analysed with the use of SPSS V.17 for Windows. We have presented categorical variables as count (percentages) and quantitative variables as mean (SD) or median (25th–75th centiles). The group’s comparison used χ² tests for categorical variables and Student t test or non-parametric equivalents for quantitative variables. Logistic regressions were then used to investigate the determinants of persisting chronic respiratory signs. Potential candidate determinants were first investigated in univariate analysis. Significant predictors (based on a threshold probability <0.1) were entered all together in the same multivariable model. A p value <0.05 was used to characterise statistically significant results.
frequency of at least one persisting chronic respiratory sign was 52% in patients with normal FEF25–75% and 74.6% among those with low FEF25–75% (p=0.005). The related OR was 2.72 (95% CI 1.33 to 5.57).

**Predictors of persisting respiratory signs at the completion of antituberculosis treatment**

Univariable and multivariable adjusted determinants of persisting respiratory signs are shown in table 3. There is no association between smoking volume (pack-years) and persistent CRS (data not shown). Independent predictors of persisting signs were longer duration of symptoms prior to tuberculosis diagnosis (OR 2.91 (95% CI 1.91 to 7.60) for symptoms of duration greater than 12 weeks) and DAO (2.22 (1.13 to 4.38)).

**Relationship of FEF25–75% with other spirometry indices**

In this study, FEV1 and FVC were significantly low in patients with low or intermediate FEF25–75% compared to those with normal FEF25–75% (p<0.001). The ratio FEV1/FVC was higher in patients with normal FEF25–75% (0.89) than in those with intermediate (0.86) or low FEF25–75% (0.81) (table 2).

**DISCUSSION**

The main findings from this study conducted among patients successfully treated for pulmonary tuberculosis in a region of medium endemicity for tuberculosis are the following: (1) the prevalence of persisting chronic respiratory signs after treatment is very high; (2) about two in five patients with normal FEV1/FVC have DAO; (3) DAO is more frequent among patients with persisting chronic respiratory signs after antituberculosis treatment and (4) long duration of symptoms prior to tuberculosis diagnosis is a predictive factor for persisting respiratory signs following successful treatment for tuberculosis.

Functional post-tuberculosis sequels have been largely characterised. However, few studies have reported on persisting chronic respiratory signs following the treatment of pulmonary tuberculosis. Even in the absence of functional sequels, post-tuberculous persisting chronic respiratory signs can negatively impact on the quality of life of individuals. In our series, three-fifths of patients had persisting chronic respiratory signs following treatment for pulmonary tuberculosis. In a recent review from South Africa, chronic bronchitis and dyspnoea were 2–7 times more frequent in people with a history of tuberculosis than in those who had never had tuberculosis.

Persisting chronic respiratory signs were associated with prolonged duration of symptoms prior to tuberculosis diagnosis in our study. Lee et al also found that the presence of bronchial obstruction in the post-pulmonary tuberculosis treatment period was influenced by the duration of symptoms prior to starting treatment. Distal bronchial obstruction was found in over a third of our participants. It was independently associated with persisting chronic pulmonary signs, and further associated with a worse profile of spirometry indices. These independent associations suggest that, in addition to confirming the bacteriological cure of the infection, people completing treatment for pulmonary tuberculosis should also be investigated for the presence of functional respiratory signs and indicators of distal airways lesions, in order to optimise their management. There are several inter-related mechanisms to explain the

occurrence of post-tuberculous distal bronchial obstruction. Bronchial endothelial inflammation during pulmonary tuberculosis could lead to localised or generalised bronchial obstruction, pulmonary fibrosis and increase airways resistance. The destruction of the lung parenchyma could also reduce the pulmonary compliance and cause the small airways to collapse.\

The cross-sectional nature is the main limitation of this study, precluding any inference about the direction of the relationships found in the study. However, in a historical cohort, Hnizdo et al. found a gradual decrease in the pulmonary function with increasing episodes of tuberculosis. It is most likely that DAO in our study was the consequence of pulmonary tuberculosis, considering that all patients with known chronic bronchitis prior to tuberculosis occurrence were excluded. The relatively large number of patients included is a major strength.

In conclusion, low FEF_{25–75}\% is a useful criterion for diagnosing distal airflow obstruction in patients treated for pulmonary tuberculosis who otherwise have a normal FEV_{1}/FVC ratio. Persisting chronic respiratory signs following treatment for tuberculosis are very frequent and often associated with DAO. Furthermore, a prolonged duration of symptoms prior to starting treatment appears to be a major determinant of persisting post-tuberculous chronic respiratory signs. Sensitisation of the population to consult early with tuberculosis-like symptoms has a potential for improving early diagnosis/treatment and reduction of the prevalence of post-tuberculosis DAO.
