Association between red cell distribution width and acute pancreatitis: a cross-sectional study

Jinmei Yao, Guocai Lv

ABSTRACT

Objective: We investigated whether red cell distribution width (RDW) was associated with mortality in patients with acute pancreatitis (AP).

Design: A cross-sectional study.

Setting: Patients with AP were recruited in the emergency department and healthy individuals were recruited in healthcare centre in the First Affiliated Hospital of Zhejiang University.

Participants: A total of 106 patients with AP and 204 healthy individuals were enrolled.

Primary and secondary outcome measures: Haematology and biochemistry results of the first test after admission were collected. The significance of the differences in RDW values among healthy individuals, non-survivors of patients with AP, and survivors of patients with AP was determined using one-way analysis of variance. Patients with AP were divided into three groups according to RDW tertiles. All patients with AP were followed up for at least 3 months. Receiver-operating characteristic (ROC) curve analysis and Kaplan-Meier analysis were used to evaluate RDW values to predict mortality of patients with AP.

Results: The RDW values were non-survivors of patients with AP>healthy individuals>survivors of patients with AP. Patients with AP with the highest RDW tertiles had the lowest levels of Ca, total protein, albumin, haemoglobin, white and red blood cell count, but the highest mortality. The area under the ROC curve of RDW was 0.846 (95% CI 0.727 to 0.964, p<0.001). With a cut-off value of 14.2 for RDW, sensitivity and specificity of RDW to predict mortality were 75.0% and 89.8%, and Kaplan-Meier analysis showed an increase in probability of death with high RDW values.

Conclusions: There is significant association between RDW and mortality of patients with AP.

INTRODUCTION

Red cell distribution width (RDW) is a widely used laboratory parameter for the quantification of the extent of erythrocyte anisocytosis, which is calculated by dividing SD of red blood cells (RBCs) volume by mean corpuscular volume (MCV) and multiplying by 100 to express the results as percentages, and reflects the variability of the size of the circulating erythrocytes. RDW is a traditional marker of excluding iron deficiency anaemia in case serum ferritin does not accurately indicate the total iron store, and plays a role in the differential diagnosis of anaemia. Recent studies have reported that RDW as a strong and independent prognostic marker has been used in many pathophysiological conditions, such as cardiovascular diseases, pulmonary diseases, rheumatoid arthritis and progressive inflammatory status, and even cancer.

Acute pancreatitis (AP), classified into mild acute pancreatitis (MAP) and severe acute pancreatitis (SAP), is a common surgical acute abdomen. AP is often complicated with systemic inflammatory response syndrome and multiple organ failure, and the mortality rate in patients with AP is about 5–10%, in SAP about 10–30% in China. Early predictive scores of SAP included Ranson and APACHE II scores, the testing parameters in the two scores are expensive, operation trial, and not conducive to clinical implementation. The study of Wang et al. indicated some inexpensive and operation easy predictive factors had been used to predict the mortality of AP. RDW value has scarcely been investigated as...
a potential biomarker of AP. Therefore, we aimed to investigate whether RDW was associated with the mortality of patients with AP.

**MATERIALS AND METHODS**

**Patients**

The study included 106 patients with AP admitted to the emergency department of the First Affiliated Hospital of Zhejiang University between 30 May 2011 and 30 May 2013, and 212 healthy individuals without chronic disease and abnormal physical examination matched for age, sex and race. Eight healthy individuals were excluded due to the absence of serum biochemistry and/or blood cell count. Patients with AP were included in the study according to the guidelines of diagnosis and treatment of AP established by the Branch of Gastroenterology, Chinese Medical Association in 2003.12 The diagnosis of AP was as follows: (1) prolonged abdominal pain characteristic of AP; (2) elevated serum amylase (Amy) and/or lipase levels by at least threefold that of normal range and (3) characteristic findings of AP on abdominal ultrasonography and/or CT scan. MAP is characterised by the absence of organ failure and the absence of local or systemic complications.12 SAP is characterised by persistent single or multiple organ failure, and usually accompanied by one or more local complications.12

**Assays**

Demographic data, aetiology of pancreatitis, hospitalisation time, laboratory serum biochemistry and complete blood cell count measures were recorded on admission. We collected samples from the 106 patients with onset of AP within 24 h for haematology and biochemistry detection on admission. White cell count (WCC), RBC count, platelet (PLT) count, RDW, haemoglobin (Hgb) level, MCV and mean platelet volume (MPV) were determined using the XE-2100 automated haematology analyser (Sysmex, Kobe, Japan) with Sysmex reagents (Sysmex). The normal reference range for RDW in the laboratory of our hospital is 11.6–15%. Serum Amy, creatinine (Cr), blood urea nitrogen (BUN), total protein (TP), albumin (Alb), total calcium (Ca), total bilirubin (TB), glucose (Glu), lactate dehydrogenase (LDH), aspartate aminotransferase (AST) and alanine aminotransferase (ALT) activities levels were determined with a Hitachi 7600 (Hitachi High-Technologies, Tokyo, Japan) using Roche reagents (Roche Diagnostics, Indianapolis, Indiana, USA).

**Statistical analyses**

RBC, PLT, RDW, Hgb, MCV, MPV, TP, Alb, Glu, Ca and LDH values were normally distributed and reported as the mean±SD. WCC, Cr, BUN, TB, ALT, AST, Amy and AP hospital stay were not normally distributed and were therefore reported as the median (range). The significance of the differences in the haematology and biochemistry results between AP and healthy control groups, patients with SAP and MAP or non-survivors and survivors of patients with AP were determined using a Student t test or Mann-Whitney U test where appropriate. The significance of differences in the haematology and biochemistry results among healthy individuals, SAP and MAP, and among non-survivors of healthy individuals, non-survivors of AP and SAP were determined using Kruskal-Wallis H test where appropriate. The significance of difference in gender was compared using χ² test. The participants were categorised into one of three subgroups depending on their RDW tertiles. To compare the variables between these subgroups, analysis of variance or Kruskal-Wallis H test were used where appropriate. Pearson partial correlation coefficients were computed to present the association between RDW values and other variables. Receiver-operating characteristic (ROC) curve analysis was used to evaluate the values for RDW to predict mortality. The survival curve for the mortality of patients with AP was drawn by Kaplan-Meier analysis. The probability cut-off points for the optimal combination of sensitivity and specificity were determined by the Youden index. Statistical analyses were performed with SPSS V.16.0 (SPSS Inc, Chicago, Illinois, USA). All statistical tests were two-tailed with p values <0.05 considered as significant.

**RESULTS**

**Characteristics of study population**

Clinical characteristics of MAP, SAP and healthy individuals are summarised in table 1. There was no difference in the gender, serum BUN and PLT count among MAP, SAP and healthy individuals, and there were significant differences in age, serum Cr, TB, ALT, Ca, Amy, TP, Alb, LDH, Glu levels, WCC, RBC count, Hgb, MCV, MPV and RDW at the first test after admission. The RDW was 12.6±0.59 and significantly lower in patients with MAP than in healthy individuals (13.42±0.85%, p<0.001); however, the RDW was 14.4±1.06 and significantly higher in patients with SAP than in healthy individuals (13.42±0.85%, p<0.001).

**Association of RDW and 3-month mortality in AP**

All patients with AP were divided into three groups according to RDW tertiles (group 1: RDW >13.3%, group 2: RDW 12.6–13.3% and group 3: RDW <12.6%), the clinical characteristics of AP according to RDW tertiles are shown in table 2. AP with RDW >13.3% had lower levels of Ca, TP, Alb, Hgb, WCC and RBC count, but higher mortality (6/8). The median hospital stay was 14 days (range 2–75 days); eight patients died during the 3-month follow-up period. The Pearson correlations indicated the correlations between RDW and the age, and biochemical and hematological parameters. In all patients with AP, RDW correlated inversely with Alb (r=−0.254, p=0.009), Ca (r=...
RDW is a novel prognostic marker that may reflect an underlying inflammatory state. AP is an inflammatory disease, and its mechanism is still not completely understood and early pathophysiological events escape clinical observation. Early deaths (within the first week) due to severe AP is generally caused by massive inflammatory responses, which result in multiple organ failure, and late deaths (after 1–3 weeks) is caused by multiple organ dysfunction with infections and sepsis. Recent studies found that RDW for predicting mortality were observed in cardiovascular diseases, acute dyspnoea and pulmonary diseases.

In our study, patients with MAP had significantly lower RDW values compared with healthy individuals, mainly because 80 MAP had lower RDW values in 106 patients with AP compared with healthy participants. The mechanisms that underly this outcome is unclear. Narci et al. found a significantly lower RDW level in patients with acute appendicitis compared with those in the control group, and RDW was not correlated with CRP and WCC. They only considered that RDW level in acute appendicitis was significantly lower than that in chronic inflammatory conditions may be lower than that in chronic inflammatory diseases, but did not clearly explain the mechanisms why acute appendicitis patients had lower RDW than the healthy group. The reasons why survivors of patients

### DISCUSSION

RDW is a quantitative measure of variability in the size of circulating erythrocytes with higher values reflecting greater heterogeneity in cell sizes. The high level of RDW is a novel prognostic marker that may reflect an underlying inflammatory state. AP is an inflammatory disease, and its mechanism is still not completely understood and early pathophysiological events escape clinical observation. Early deaths (within the first week) due to severe AP is generally caused by massive inflammatory responses, which result in multiple organ failure, and late deaths (after 1–3 weeks) is caused by multiple organ dysfunction with infections and sepsis. Recent studies found that RDW for predicting mortality were observed in cardiovascular diseases, acute dyspnoea and pulmonary diseases.

In our study, patients with MAP had significantly lower RDW values compared with healthy individuals, mainly because 80 MAP had lower RDW values in 106 patients with AP compared with healthy participants. The mechanisms that underly this outcome is unclear. Narci et al. found a significantly lower RDW level in patients with acute appendicitis compared with those in the control group, and RDW was not correlated with CRP and WCC. They only considered that RDW level in acute appendicitis was significantly lower than that in chronic inflammatory conditions may be lower than that in chronic inflammatory diseases, but did not clearly explain the mechanisms why acute appendicitis patients had lower RDW than the healthy group. The reasons why survivors of patients

‡Mann-Whitney U test.
As far as we know, only one study by Şenol et al. described that RDW on admission was a predictor of mortality in Turks with AP. The mechanisms underlying the association between RDW and mortality in AP are unclear. Some studies indicated that RDW may also be related with inflammation, and not only with anaemia. Moreover, RDW has been found to be strongly associated with inflammatory markers (eg, CRP or erythrocyte sedimentation rate) in a large cohort of unselected outpatients. Elevated levels of inflammatory cytokines and alterations in iron metabolism together with inflammatory states may decrease endothelial nitric oxide production, which is known to stimulate the proliferation of erythroid progenitor cells, and be implicated in the development of anaemia and change of RDW. However, after adjustment for CRP, Zhang et al. found that RDW was independently associated with in-hospital mortality (OR 1.1, p=0.002). On the basis of a multi-ethnic population, Veeranna et al. also found that RDW (HR 1.26, p<0.001) may be considered a stronger biomarker for coronary heart disease mortality than CRP (HR 1.18, p=0.077), after further analysis of mortality prediction in categorised CRP subgroups, RDW remained a significant predictor in the CRP subgroups (≤ and >3 mg/L).

A few limitations warrant consideration. First, we did not investigate the causes of elevated RDW values in non-survivors of patients with AP. Second, our study was a small sample size and single-centre study. Therefore, future large-size and multicentre studies are required to further clarify whether RDW is a predictor in patients with AP.

In conclusion, our results indicated that the RDW values were non-survivors of patients with AP>healthy individuals>survivors of patients with AP; patients with AP with the highest RDW tertiles had the highest mortality and the non-survivors of AP had higher RDW values when compared with survivors, and a cut-off value of 14.2 for RDW to predict mortality.
