ABSTRACT

Objectives The aim of this study was to investigate the association of serum fibrinogen with cardiovascular events (CVE) in Chinese patients with type 2 diabetes mellitus (T2DM) and stable coronary artery disease (CAD).

Design An observational study.

Setting FuWai Hospital in Beijing, China.

Participants A cohort of 1466 patients with T2DM and angiographic-proven stable CAD was evaluated.

Outcome measures Baseline serum fibrinogen levels were measured and trisected into 'low', 'middle' and 'high'. Their association with CVE was explored using Cox proportional hazard models.

Results With 20.2 months (average) follow-up, 44 (3%) were lost to follow-up and 96 patients developed CVE. Compared with the patients without CVE, the ones who developed CVE had higher levels of fibrinogen. Univariable regression revealed a significant relation of fibrinogen to CVE (HR (HR) 1.25, 95% CI 1.06 to 1.47, p=0.010) per SD increase of fibrinogen at baseline. After adjusting for multiple established cardiovascular disease (CVD) risk factors, the association persisted (HR 1.30, 95% CI 1.11 to 1.56, p=0.004). Moreover, after adjusting for CVD risk factors, the HRs for middle-serum and high-serum fibrinogen concentration, using ‘low’ group as reference, were 1.23 (95% CI 0.69 to 2.20) and 2.20 (95% CI 1.11 to 4.36, p=0.049).

Conclusions We first indicated that elevated fibrinogen level was independently associated with increased CVE in Chinese patients with T2DM and stable CAD.

INTRODUCTION

Fibrinogen, as a marker of thrombosis and inflammation, is associated with cardiovascular diseases (CVD). It has been demonstrated that elevated fibrinogen level is significantly associated with intima-media thickness and subclinical atherosclerosis.\(^1\)\(^-\)\(^3\) Also, previous study revealed that fibrinogen independently predicted future ischaemic stroke risk and incident hypertension.\(^4\)\(^-\)\(^8\) What is more, fibrinogen has been well established to be a strong and independent cardiovascular risk factor in general population.\(^8\)\(^-\)\(^12\) Data suggested that baseline plasma fibrinogen level could predict cardiovascular events (CVE) in general individuals and non-diabetics.\(^3\)\(^,\)\(^9\)\(^-\)\(^13\)

It is worthy of mentioning that individuals with type two diabetes mellitus (T2DM) have higher levels of plasma fibrinogen compared with those without T2DM.\(^8\)\(^-\)\(^14\) The most common cause for mortality in patients with DM is coronary artery disease (CAD). Thereby, it is logically hypothesised that hyperfibrinogenaemia could contribute to increase CVE in this disease. However, studies on the role of fibrinogen in cardiovascular outcomes in diabetes are both limited and controversial.\(^5\)\(^-\)\(^15\)\(^-\)\(^17\)

Based on such situation and combined with a fact that no data are currently available so far with regard to the relationship between fibrinogen and CVE in patients with T2DM and stable CAD, we, therefore, performed a prospective observational study of the association of baseline plasma fibrinogen and the risk of CVE in patients with diabetes and stable CAD.

Strengths and limitations of this study

- We, for the first time, reported that baseline fibrinogen was associated with cardiovascular events (CVEs) in Chinese patients with type 2 diabetes (T2DM) and stable coronary artery disease (CAD).
- The number of CVEs was relatively small and the follow-up duration was relatively short, so further study is needed.
- We just investigated whether the one-time baseline level of fibrinogen was a predictor of short-term outcome in patients with T2DM and stable CAD.

Patients and methods

Study population

In this study, consecutive patients hospitalised in our division were screened between April 2011 and July 2015 for the following inclusion criteria: over the age of 18 years, T2DM and angiographic-proven stable CAD. Exclusion criteria were acute coronary syndrome (ACS), in-hospital cardiac death at first admission in our division, unavailable data of baseline fibrinogen concentration, the existence of any infectious or systematic inflammatory diseases, significant haematologic disorders, thyroid dysfunction, severe liver insufficiency (transaminases >10 times upper reference levels) and/or severe renal insufficiency (end-stage renal disease or chronic dialysis treatment) and malignant tumours. According to the inclusion and exclusion criteria, a total of 1466 eligible patients were enrolled (figure 1). The study was performed according to the Declaration of Helsinki, and the hospital ethics review board (Fuwai Hospital and National Center for Cardiovascular Diseases, Beijing, China) approved the protocol. All the subjects gave written informed consent.

Biochemical analysis and baseline examination

Overnight fasting blood samples were drawn from each patient at admission and centrifuged at room temperature within 2 hours. As described in our previous studies, the plasma levels of fibrinogen were quantitatively measured by the method of Clauss and a Stagoauto analyser with STA Fibrinogen kit (Diagnostic Stago, Taverny, France). Glucose, haemoglobinA1c (HbA1c), uric acid and lipid profile were determined by standard methods. The concentrations of high-sensitivity C-reactive protein (hs-CRP) were determined using immunoturbidimetry (Beckmann Assay 360, Bera, California, USA).

Height and weight were measured, and body mass index (BMI) (kg/m²) was calculated. DM was defined as a fasting plasma glucose ≥126 mg/dL (7.0 mmol/L) in multiple determinations and/or the current use of medication for diabetes. Hypertension was defined as repeated blood pressure measurements ≥140/90/90 mm Hg (at least two times in different environments) or currently taking anti-hypertensive drugs. Stable CAD was defined as typical angina-like chest pain brought on by exertion and relieved by rest or sublingual nitrates or both, a positive treadmill exercise test (>1 mm ST-segment depression) and stable obstructive lesion >50% in at least one of the three major coronary arteries or major branches assessed by at least two independent senior interventional cardiologists who had no knowledge of the patients’ clinical characteristics and biochemical results. Dyslipidaemia was considered to be present in patients if they had fasting total cholesterol ≥200 mg/dL or triglyceride ≥150 mg/dL.
Definition of events and follow-up
The primary outcomes were CVE. CVE were defined as the cardiac death, stroke, non-fatal myocardial infarction (MI), postdischarge revascularisation (percutaneous coronary intervention (PCI)/coronary artery bypass grafting (CABG)) due to clinical deterioration or unstable angina (UA). The follow-up data collection was performed by the trained nurses or cardiologists who were blinded to the aim of this study by means of standardised telephone interviews at 6-month intervals. Follow-up time was calculated as the number of months from the enrolment up to the last traceable hospital outpatient or inpatient record or telephone interview before March 2016, and was censored on the date of

ACEI/ARB, angiotensin-converting enzyme inhibitor/angiotensin II receptor blocker; Apo, apolipoprotein; CVE, cardiovascular events; eGFR, estimated glomerular filtration rate; HbA1c, glycosylated haemoglobin type A1C; HDL, high-density lipoprotein; hs-CRP, high-sensitivity C-reactive protein; LDL, low-density lipoprotein; OADs, oral antidiabetic drugs.
the first CVE. Death of a participant was reported by relatives or the general practitioner who treated the participant. Three experienced physicians who were blinded to any of the study data independently classified the events.

**Statistical analysis**

Continuous variables were presented as mean±SD or median (25th, 75th percentiles) and categorical variables as percentages. Fibrinogen levels were trisected into ‘low’ (≤2.91 g/L), ‘middle’ (2.91–3.51 g/L) and ‘high’ (≥3.51 g/L). Comparisons of continuous baseline data between two or more groups were performed with Student t-test and analysis of variance, respectively, and χ2 test was used to compare categorical data. Kruskal-Wallis H test was used for non-normal variables. Test for linear trend (Jonckheere-Terpstra test) was performed by assigning median value for each tertile and treated as continuous variables.

Participants who were lost during follow-up were treated as censored observations and not used for follow-up analysis. Using the Cox proportional hazards model, HRs of CVE, with 95% CIs were calculated using crude models as well as models adjusted for potential confounding factors. A p<0.05 for two-sided testing was considered statistically significant. The statistical analysis was performed with SPSS V.19.0.

**RESULTS**

**Baseline characteristics**

The baseline demographic, clinical characteristics and laboratory findings of the study cohort classified by outcome status (with CVE or not) were listed in table 1. Compared with the patients without CVE, the ones who developed CVE had lower left ventricle ejection fraction (LVEF) but higher levels of fibrinogen, HbA1c, hs-CRP and uric acid. Meanwhile, we found that there is a tendency to higher fasting triglyceride level in CVE group (p=0.054). In addition, there is no significant difference in age, BMI, gender, status of hypertension, smoking status and medical history between the patients with or without CVE.

Table 2 compared the baseline cardiovascular risk profiles of the study population, divided into ‘low’ (≥2.91 g/L), ‘middle’ (2.91–3.51 g/L) and ‘high’
(≥3.51 g/L) subgroups on the basis of the fibrinogen concentration. The patients with middle and high levels of fibrinogen had higher percentage of CVE, female and higher levels of hs-CRP, total cholesterol, low-density lipoprotein cholesterol (LDL-C), HbA1c and fasting glucose compared with the ‘low’ group. No significant difference was found in age, BMI, blood pressure and smoking status.

Outcomes
The average follow-up time was 20.2 months (range from 0.4 to 49.3). During the follow-up period, 96 patients experienced cardiovascular event: 19 (19.8%) non-fatal MIs, 55 (57.3%) myocardial revascularisation procedures (PCI or CABG) because of clinical deterioration, 15 (15.6%) strokes and 7 (7.3%) cardiac deaths. We calculated the number of new events per 100 person-years, namely, 2.0047/100 per 100 person-years. Patients who suffered ACS and underwent revascularisation procedures were assigned once in the analysis. Of the 1466 patients with diabetes and stable coronary artery disease, 44 (3%) were lost to follow-up. Therefore, the data of 1422 participants were used for follow-up analysis.

HRs of fibrinogen for study outcomes
Univariable regression revealed significant association between serum fibrinogen level at baseline and CVE (HR=1.25, 95% CI 1.06 to 1.47, p=0.010) per SD increase of serum fibrinogen at baseline. After adjusting for multiple established CVD risk factors, the association persisted (HR=1.30, 95% CI 1.02 to 1.66, p=0.037) (table 3). Unadjusted HR for developing a CVE was significantly increased in the ‘high’ group compared with the ‘low’ group at baseline, and similar results were also found after adjusting for sex and age (figure 2). After adjusting for established CVD risk factors, the HR for middle and high serum fibrinogen concentration, using ‘low’ group as reference, were 1.23 (95% CI 0.69 to 2.20) and 2.20 (95% CI 1.11 to 3.36) (p for trend 0.049) (table 3).

DISCUSSION
In this prospective observational study in single centre with a relative large sample size, we, for the first time, found that baseline fibrinogen concentration was independently associated with CVE in Chinese patients with T2DM with stable CAD. Although the study might be limited by follow-up duration, the present data provided novel and important information with regard to the key issue whether the baseline fibrinogen concentration

can be a marker for predicting the clinical outcomes in patients with T2DM and stable CAD.

Sufficient evidence has demonstrated that plasma fibrinogen is a risk factor for CVD in general population, but the role of fibrinogen in diabetes remains controversial. Some previous studies demonstrated that hyperfibrinogenaemia was an important risk factor for vascular complications in diabetes. For instance, a prospective cohort of 2329 patients with T1DM revealed that fibrinogen was significant and independent predictor of coronary heart disease in men. Moreover, increased fibrinogen level was shown to be associated with diabetic nephropathy in patients with T2DM and T1DM. Gargano Heart Study showed that fibrinogen was a predictor of incident major CVE after adjusting for sex, age, smoking habit and BMI in patients with diabetes. In parallel, Bruno et al reported that fibrinogen had an independent predictive effect on cardiovascular mortality in T2DM. Furthermore, Stehouwer et al revealed that baseline fibrinogen concentrations were strongly and independently associated with risk of all-cause death in patients with T2DM. On the contrary, some studies reported that the association between fibrinogen and incident CAD in patients with T2DM was non-significant via multivariable analyses.

As we well known, the major cause of death in T2DM is macrovascular complications, especially CAD. Hence, in this study, we enrolled angiographic-proven CAD patients with T2DM and tried to examine the role of fibrinogen in such a study population of patients with T2DM and CAD. We found that elevated fibrinogen level at baseline was associated with increased CVE in patients with T2DM and stable CAD. In addition, we also found that fibrinogen was higher among those patients who developed a cardiovascular event compared with those who did not, which is in agreement with previous studies. To our knowledge, this is the first time to investigate the relationship between fibrinogen and CVE in patients with T2DM and stable CAD.

Recently, the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) study reported that baseline fibrinogen level was associated with an increased risk of macrovascular events and death in univariate analysis, but after further adjustment, fibrinogen was not an independent predictor of macrovascular. In this study, our finding is not consistent with the ADVANCE study, and we speculate that some reasons could explain it. First, the inclusive criteria are different: we chose the patients with T2DM and stable CAD, while the ADVANCE study chose the subjects with T2DM and a history of CVD (stroke, myocardial infarction, transient ischaemic attack, unstable angina, coronary or peripheral revascularisation, amputation, macroalbuminuria, proliferative retinopathy or photocoagulation, macular oedema or blindness in one eye) or one or more additional cardiovascular risk factors. Second, despite the patients from many countries in the ADVANCE study, Chinese and Indians were excluded. Actually, there are ethnic differences in fibrinogen levels. Thus, whether the results also persist in Chinese is undetermined. Finally, the definitions of outcomes are different. In ADVANCE study, major macrovascular events were cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke, while our cardiovascular events were defined as cardiac death, stroke, non-fatal MI, postdischarge revascularisation (PCI/CABG) due to clinical deterioration or UA. In addition, our previous cross-sectional study has revealed that plasma fibrinogen is associated with severity of CAD evaluated using Gensini score in patients with diabetes, which partly supports our present finding. Furthermore, in this study, we found that 3.515 (g/L) is a cut-off value of fibrinogen to predict CVEs in our cohort, which is consistent with previous study.

There were several limitations of this study. First, the number of events is relatively small to assess the prognostic value of fibrinogen. The conclusion needs to be testified by large-scale study in the future. Second, the follow-up duration was relatively short and longer follow-up will be required. Third, this sample population was collected prospectively from a single centre in China. Fibrinogen varies in race, so we do not know if our results would apply to other ethnic groups and studies from multiple centres are needed to test our finding. Finally, we just collected one-time baseline level of fibrinogen.

In conclusion, we found that fibrinogen was associated with CVE in Chinese patients with T2DM and stable CAD. Further studies are required to clarify the issue completely.
