**Running title:** Transmissibility of the 2009 H1N1 pandemic

## Abstract

**Objectives:** During the first wave of the 2009 influenza pH1N1, disease burden was distributed in a geographically heterogeneous fashion. It was particularly high in some remote and isolated Canadian communities when compared to urban centres. We sought to estimate the transmissibility (the basic reproduction number) of pH1N1 strain in some remote and isolated Canadian communities.

**Design:** A discrete time susceptible-exposed-infected (SIR) transmission model to was fit to infection curves simulated from laboratory-confirmed case counts for pH1N1 on each day. Sampling from Poisson distribution was used to estimated the basic reproduction number,  $R_0$ , of pH1N1 during the spring wave for five different communities in Manitoba and Nunavut,

1  
2  
3 Canada, where remote and isolated communities experienced a high incidence of infection, and  
4  
5 high rates of hospitalization and intensive care unit (ICU) admission.  
6  
7

8  
9 **Setting:** Remote and isolated communities in Northern Manitoba, Nunavut, and the largest  
10  
11 urban centre (Winnipeg) in the province of Manitoba, Canada.  
12

13  
14 **Results:** Using published values of the exposed and infectious periods specific to H1N1  
15  
16 infection, corresponding to the average generation time of 2.69 days, we estimated a mean  
17  
18 value of 2.25 for  $R_0$  (95% CI: 1.10–4.25) in a community located in northern Manitoba.  
19

20  
21 Estimates of  $R_0$  for other communities in Nunavut varied considerably with higher mean values  
22  
23 of 4.38 (95% CI: 2.83–6.76); 2.23 (95% CI: 1.46–4.44); and 2.62 (95% CI: 1.65–4.02). We  
24  
25 estimated a lower mean value of 1.62 (95% CI: 1.38–2.00) for  $R_0$  in the Winnipeg health region,  
26  
27 as the largest urban centre in Manitoba.  
28  
29

30  
31  
32  
33 **Conclusions:** Influenza pH1N1 appears to have been far more transmissible in rural and isolated  
34  
35 Canadian communities than other large urban areas. The differential severity of the pandemic  
36  
37 in these regions may be explained partly by differential transmissibility, and suggests the need  
38  
39 for more nuanced, targeted, or population specific control strategies in Canada.

## Introduction

Early outbreaks of the 2009 H1N1 influenza pandemic displayed variable degrees of incidence, apparently higher attack rates, and more severe disease outcomes in several remote and isolated communities in Canada [1,2]. Epidemiological data collected during the first wave of H1N1 pandemic indicate disproportionately higher rates of hospitalization and intensive care unit (ICU) admission in these communities. For instance, hospitalization rates in Nunavut and northern Manitoba were 2.44 and 1.27 per 1,000 population, respectively, which are significantly higher than the corresponding rates for Winnipeg (0.13) or the province of Ontario (0.033). Similar differences are evident from data regarding ICU admission rates, which were higher for Nunavut (0.20) and northern Manitoba (0.16) than those for Winnipeg (0.032) and Ontario (0.0056), per 1,000 population. The differential prevalence of predisposing health conditions including diabetes, pregnancy and morbid obesity, has received considerable attention as explicators of severe outcomes of H1N1 pandemic in rural and urban communities in Canada [2]. The high rates of hospitalization and ICU admission within these remote regions, could be linked to both transmissibility of the disease and to the prevalence of factors predisposing to more severe outcomes in infected individuals.

An important index of transmissibility for a communicable disease is the basic reproduction number ( $R_0$ ) that represents the number of secondary infections generated by a single infected case in an entirely susceptible population [3]. Early published literature for the transmissibility of pandemic H1N1 infection provides a range of 1.2–1.8 for  $R_0$  [4,5,6,7], mainly in large urban settings, suggesting that the novel H1N1 strain was less transmissible than the

1  
2  
3 1918-1919 pandemic virus for which  $R_0$  has been estimated in the range 1.8–3.0 [8]. However,  
4  
5  
6 early estimates may not apply in remote and isolated communities that have distinct  
7  
8  
9 demographic characteristics, as well as distinct environmental (built or natural) conditions. We  
10  
11 sought to evaluate differential transmissibility of H1N1 in five distinct population settings in  
12  
13  
14 Canada: a remote/isolated community in the Burntwood health region of northern Manitoba,  
15  
16 three remote/isolated communities in Nunavut, and compare them with the largest urban area  
17  
18 (i.e., the Winnipeg health region) in Manitoba. Communities in Nunavut as well as several  
19  
20 communities in northern Manitoba would be considered remote and/or isolated communities  
21  
22 [9] and many of these geographic areas have predominantly Aboriginal populations (e.g., 85%  
23  
24 of the Nunavut population and 76% of the northern Manitoba region self-identify as Aboriginal)  
25  
26  
27 [10].  
28  
29  
30

### 31 **Material and Methods**

32  
33 To estimate plausible ranges for  $R_0$ , we employed a discrete time epidemic model, and  
34  
35 fitted to infection curves inferred from collected data for laboratory-confirmed cases of H1N1  
36  
37 infection during the first wave of the 2009 pandemic. Details of data and estimation procedure  
38  
39 are described below.  
40  
41  
42  
43  
44

### 45 **Case Data**

46  
47 We obtained the daily number of laboratory-confirmed cases of pandemic H1N1  
48  
49 influenza (in which the cases were reported based on the earliest date of symptom onset, initial  
50  
51 care, specimen collection, hospital admission, or ICU admission) for the period of May 3 to  
52  
53 August 5, 2009, for each community under study. A laboratory-confirmed case was reported as  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 an individual with ILI or severe respiratory illness who tested positive for pandemic H1N1  
4  
5 influenza A virus by real-time reverse-transcriptase PCR (RT-PCR) or viral culture. These data  
6  
7 were collected and provided by Manitoba Health, and the Nunavut Department of Health and  
8  
9 Social Services (HSS).  
10

### 11 **The Model**

12  
13 We considered a homogeneous mixing structure for the model in which individuals are  
14  
15 identified by their epidemiological status as susceptible ( $S$ ), exposed but not yet infectious  
16  
17 ( $E$ ), Infectious ( $I$ ), and recovered ( $R$ ). Exposed state refers to the period of time following  
18  
19 transmission of infection during which the newly infected person cannot transmit the disease  
20  
21 and symptoms are absent before developing clinical disease. Assuming that the reduction in the  
22  
23 number of susceptibles is small during the early stages of the outbreak (i.e.  $S(t)/S_0 \approx 1$ , where  
24  
25  $S_0$  is the initial number of susceptibles) [11], the number of infections at time  $t$  is given by [12]  
26  
27  
28  
29  
30  
31  
32  
33  
34

$$35 \quad I(t) \approx I_0 e^{\frac{1}{2} \left[ \sqrt{4(R_0 - 1)\sigma\gamma + (\sigma + \gamma)^2} - (\sigma + \gamma) \right] t} \quad (1)$$

36  
37 where  $\sigma$  and  $\gamma$  are the average duration of exposed and infectious stages,  $I_0$  is the initial  
38  
39 number of infectious cases, and  $R_0$  is the basic reproduction number. The expression (1)  
40  
41 describes the exponential growth of epidemic spread following disease outset. We estimated  
42  
43  $R_0$  by fitting  $I(t)$  to infection curves during the exponential phase of epidemic growth.  
44  
45  
46  
47  
48  
49  
50

### 51 **Model Parameters**

52  
53 The values of exposed and infectious periods were taken from estimated ranges in the  
54  
55 published literature specific to the 2009 pandemic, with a fixed exposed period of 1 day, and a  
56  
57  
58  
59  
60

1  
2  
3 mean duration of infectiousness of 3.38 days [11,13]. Using a common heuristic, that the  
4  
5 generation times can be estimated as the sum of the exposed period and half of the duration of  
6  
7 infectiousness[14], leads to a mean generation times of 2.69 days, which lies in the estimated  
8  
9 range for pandemic H1N1 [15,16,17] .  
10  
11

### 12 13 **Sampling**

14  
15 To determine the variability in  $R_0$ , we generated 1000 datasets for case counts on each  
16  
17 day through sampling from a Poisson distribution, with reported cases on the corresponding  
18  
19 day as the mean of distribution. To create an infection curve for each dataset, first we sampled  
20  
21 an infectious period for each case from a log-normal distribution with the scale parameter  
22  
23  $a = 1.192$  and shape parameter  $b = 0.233$ , with the 95% range of 2.13 – 5.1 days [11]. We  
24  
25 assumed that the infectious period was initiated one day before the case was confirmed  
26  
27 (reported date) [12]. This effectively means that every case was on the infection curve  $I(t)$  for  
28  
29 its sampled duration of infectiousness (Figures 1 and 2).  
30  
31  
32

34  
35  
36  
37  
38  
39  
40

### 41 **$R_0$ Estimation**

42  
43 Since the reproduction number only reflects the growth rate during the early stages of  
44  
45 the epidemic, estimating  $R_0$  is sensitive to the time period chosen for fitting the model to the  
46  
47 data [18]. For a fit with very short timelines following the onset of the outbreak (establishment  
48  
49 phase), the uncertainty in estimates of  $R_0$  will be high. On the other hand, fitting the model  
50  
51 using data that extend beyond the epidemic peak, will result in underestimating  $R_0$ , through  
52  
53 the influence of several factors, including widespread implementation of public health  
54  
55  
56  
57  
58  
59  
60

measures and an increase in herd immunity, which may in turn invalidate the assumption  $S(t) / S_0 \approx 1$ . In order to minimize these effects, we obtained the turning points of the outbreaks following the initial exponential growth phase, and performed fitting from the date at which the first laboratory confirmed case was identified, up to one day before the turning point for each infection curve. Turning point for each dataset was obtained through fitting the Richards model to cumulative number of daily counts in each infection curve [19,20]. Assuming that  $K$  represents the cumulative number of daily cases for the infection curve  $I(t)$  (generated through sampling method), the first turning point  $t_m$  was obtained by solving the equation  $I(t_m) = K(1+c)^{1/c}$ , where  $c$  is the deviation parameter estimated using the method of least squares through curve-fitting [21]. We then estimated  $R_0$  by fitting  $I(t)$  in equation (1) to the generated infection curves from the date of the first laboratory case until  $t_m - 1$ . The mean values and 95% confidence intervals were obtained from the  $R_0$  distributions.

## Results

The infection curves and the corresponding posterior distributions for the ranges of  $R_0$  are illustrated in Figures 1 and 2. The mean estimate of  $R_0$  for a northern community in Manitoba (Figure 1b) is 2.25 (95% CI: 1.10–4.25), which is higher than the estimate for Winnipeg health region with the mean value of 1.62 (95% CI: 1.38–2.00). We obtained considerably higher estimates for the mean values of  $R_0$  for other communities in the territory of Nunavut (Figures 1d,f,h): 4.37 (95% CI: 2.83 – 6.76); 2.23 (95% CI: 1.46 – 4.44); and 2.62 (95% CI: 1.65 – 4.02). Mean values of  $R_0$  stay above previous estimates for H1N1 transmission in

1  
2  
3 larger communities and urban centres [4,5,6,7]. While estimated  $R_0$  ranges considerably  
4  
5  
6 overlap, outbreaks in Nunavut appear to have been driven by somewhat higher transmissibility  
7  
8  
9 that is comparable or higher than that of the 1918 pandemic [8]. We further estimated  $R_0$  by  
10  
11  
12 creating a single dataset for northern communities in Manitoba and Nunavut. The mean value  
13  
14 of  $R_0$  was 2.27 (95% CI: 1.79-2.94), providing a significant difference (Wilcoxon signed-rank  
15  
16  
17 test:  $p < 0.001$ ) when compared with  $R_0$  estimates for the Winnipeg health region.  
18  
19

## 20 Discussion

21  
22  
23 Determining the variability in transmissibility of a novel disease in populations with  
24  
25 different demographics (e.g. age structure, household age composition, and housing density) is  
26  
27 crucial for identifying the within-community factors that have the greatest influence on disease  
28  
29 spread and, (by changing the total number of infections), its severity. Our results suggest that  
30  
31 more severe outcomes observed in the 2009 influenza A H1N1 pandemic in remote and  
32  
33 isolated communities [2] may have been due to differential transmissibility of infection,  
34  
35  
36 resulting in more rapid epidemic spread and larger numbers of individuals affected at northern  
37  
38 latitudes [22].  
39  
40  
41  
42

43  
44 Estimates of transmissibility could play an important role in determining the most  
45  
46 effective utilization of public health interventions, in particular when resources are scarce. It is  
47  
48 important to note that  $R_0$  is effectively an *exponent* that determines both epidemic growth  
49  
50 properties, the final size of an epidemic, and the fraction of individuals who need to be  
51  
52 vaccinated to achieve herd immunity. For example, the expected relative final size of an  
53  
54 epidemic with an  $R_0$  of 2.7 is 25% larger in the absence of intervention than an epidemic with  
55  
56  
57  
58  
59  
60

1  
2  
3 an  $R_0$  of 1.8; and to attain an immune herd (i.e., critical vaccination level:  $1-1/R_0$ ), the absolute  
4  
5  
6 fraction of the population vaccinated must be 19% higher in the population with the higher  $R_0$ .  
7  
8  
9 This has important public health implications for vaccination programs and suggests that  
10  
11  
12 transmissibility is an important consideration in prioritizing the allocation of limited health  
13  
14 resources.

15  
16  
17 The mechanisms underlying the differential transmissibility of a pathogen in these  
18  
19 Canadian communities are unclear, but could be related to the effectiveness of available  
20  
21 disease control programs, environmental factors including the prevalence of low quality  
22  
23 housing [23], exposure to indoor air pollutants, lack of access to clean water, and also to  
24  
25 differences in demographic characteristics, crowding, and mixing patterns. For example, the  
26  
27 average number of persons per household in the northern Manitoba region is 3.6, which is 44%  
28  
29 greater than the mean size of 2.5 persons per household in Winnipeg as the largest urban  
30  
31 centre in the same province [24,25]. The average number of people per household in Nunavut  
32  
33 is 3.8, which is higher than both northern Manitoba and Winnipeg [10]; this may therefore  
34  
35 account for a higher rate of secondary household transmission, which is known as a major  
36  
37 route for the spread of influenza infection in the wider community [26,27,28]. In addition, age  
38  
39 has been recognized as an important parameter for the spread of disease with higher rates of  
40  
41 infectious contacts among schoolchildren and younger adults. There are also differences in the  
42  
43 age profiles of the populations studied here with other urban centres. For example, the average  
44  
45 age in the northern Manitoba region is 24 and in Nunavut is 23 [10], which is approximately 15-  
46  
47 16 years younger than the average age (38.7) in Winnipeg [24,25]. In Nunavut, only 2.7% of the  
48  
49 population is greater than 65 years of age and 34% of the population is less than 15 years of age  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 [10]. Although older age has been associated with a higher risk of severe outcomes during  
4  
5  
6 seasonal influenza epidemics, pandemics (e.g., 1918, 1957) are generally characterized by high  
7  
8 rates of morbidity and mortality among younger adults [29,30], as has also been documented  
9  
10 for the 2009 H1N1 pandemic [31]. Moreover, serological studies have shown the existence of  
11  
12 cross-reactive antibody responses for individuals older than 50 years of age due to prior  
13  
14 exposure to similar viruses [32], which may reflect a reduced likelihood of H1N1 infection in  
15  
16 older populations. As was observed in other geographic regions [33], in Manitoba the 2009  
17  
18 pandemic predominantly affected young adults and children in both spring and fall waves  
19  
20  
21  
22  
23 (Figure 3).  
24

25  
26 In populations with low mean age (such as Nunavut), the buffering effect of pre-existing  
27  
28 immunity in older individuals is less pronounced, which may contribute to higher  
29  
30 transmissibility of the virus. In remote and isolated communities in Canada, climate, healthcare  
31  
32 capacity in the community, socioeconomic status, health status, presence of vulnerable groups  
33  
34 (e.g. children < 5 years of age, immunocompromised, and pregnant women), limited numbers  
35  
36 of healthcare workers in the community, equipment and facilities, medical transportation and  
37  
38 other critical infrastructure such as housing also play a role in determining differential epidemic  
39  
40  
41  
42  
43  
44 impact [34].  
45

46  
47 The model employed in this study is subject to limitations, including the simplifying  
48  
49 assumption of homogeneity in the population interactions. Some of the limitations are imposed  
50  
51 by the lack of specific data, which precludes the use of more complex models with network  
52  
53 structure or age-stratified populations. The simple model structure does not elucidate the  
54  
55 specific mechanisms driving increased transmissibility in these communities. However,  
56  
57  
58  
59  
60

1  
2  
3 empirical evidence to support the observation of increased transmissibility in these  
4  
5 communities clearly demonstrates the need for ongoing research in order to identify the  
6  
7 specific mechanisms. Due to uncertainties in the level of pre-existing immunity and its  
8  
9 distribution in different age-segments of the population, we did not include the effect of  
10  
11 immune responses in our model. However, considering prior immunity [35] we would expect to  
12  
13 estimate greater values for  $R_0$  compared to when the entire population is assumed to be  
14  
15 susceptible. Finally, our model considers these communities without considering travel or  
16  
17 interactions with other population settings in the same region. It is possible that some influenza  
18  
19 cases were undiagnosed and thus not captured in surveillance data; this would lead us to  
20  
21 underestimate the transmissibility of the virus, making our estimates “lower bound” estimates.  
22  
23  
24 We would expect underreporting to be less likely in the first wave of the pandemic (the time  
25  
26 period that we examined) than the second wave, as individuals with influenza-like illness  
27  
28 symptoms were encouraged to seek medical care, especially in remote and isolated  
29  
30 communities. In the absence of data for the true burden of the disease, we used laboratory  
31  
32 confirmed case counts, which may be subject to biases due to differential rates of testing  
33  
34 between different age groups, different geographic regions, and over time. However, it is  
35  
36 difficult to assess the magnitude and direction of such biases. Data available for this study did  
37  
38 not provide any relevant information on other potential confounders that could be included in  
39  
40 our estimation model. Despite these limitations, our results suggest that there is indeed a  
41  
42 considerable difference between the reproduction numbers of H1N1 outbreaks in remote and  
43  
44 isolated communities and urban centers. Further investigation is required to explore the  
45  
46 underlying mechanistic reasons for this differential transmissibility, which could determine  
47  
48  
49  
50  
51

**Running title:** Transmissibility of the 2009 H1N1 pandemic

## Abstract

**Objectives:** During the first wave of the 2009 influenza pH1N1, disease burden was distributed in a geographically heterogeneous fashion. It was particularly high in some remote and isolated Canadian communities when compared to urban centres. We sought to estimate the transmissibility (the basic reproduction number) of pH1N1 strain in some remote and isolated Canadian communities.

**Design:** A discrete time susceptible-exposed-infected (SIR) transmission model to was fit to infection curves simulated from laboratory-confirmed case counts for pH1N1 on each day. Sampling from Poisson distribution was used to estimated the basic reproduction number,  $R_0$ , of pH1N1 during the spring wave for five different communities in Manitoba and Nunavut,

1  
2  
3 Canada, where remote and isolated communities experienced a high incidence of infection, and  
4  
5 high rates of hospitalization and intensive care unit (ICU) admission.  
6  
7

8  
9 **Setting:** Remote and isolated communities in Northern Manitoba, Nunavut, and the largest  
10  
11 urban centre (Winnipeg) in the province of Manitoba, Canada.  
12

13  
14 **Results:** Using published values of the exposed and infectious periods specific to H1N1  
15  
16 infection, corresponding to the average generation time of 2.78 days, we estimated a mean  
17  
18 value of 2.26 for  $R_0$  (95% CI: 1.57–3.75) in a community located in northern Manitoba.  
19

20  
21  
22 Estimates of  $R_0$  for other communities in Nunavut varied considerably with higher mean values  
23  
24 of 3.91 (95% CI: 3.08–4.87); 2.03 (95% CI: 1.50–3.19); and 2.45 (95% CI: 1.68–3.44). We  
25  
26  
27 estimated a lower mean value of 1.57 (95% CI: 1.35–1.87) for  $R_0$  in the Winnipeg health region,  
28  
29  
30 as the largest urban centre in Manitoba.  
31

32  
33 **Conclusions:** Influenza pH1N1 appears to have been far more transmissible in rural and isolated  
34  
35 Canadian communities than other large urban areas. The differential severity of the pandemic  
36  
37 in these regions may be explained partly by differential transmissibility, and suggests the need  
38  
39  
40 for more nuanced, targeted, or population specific control strategies in Canada.

## Introduction

Early outbreaks of the 2009 H1N1 influenza pandemic displayed variable degrees of incidence, apparently higher attack rates, and more severe disease outcomes in several remote and isolated communities in Canada [1,2]. Epidemiological data collected during the first wave of H1N1 pandemic indicate disproportionately higher rates of hospitalization and intensive care unit (ICU) admission in these communities. For instance, hospitalization rates in Nunavut and northern Manitoba were 2.44 and 1.27 per 1,000 population, respectively, which are significantly higher than the corresponding rates for Winnipeg (0.13) or the province of Ontario (0.033). Similar differences are evident from data regarding ICU admission rates, which were higher for Nunavut (0.20) and northern Manitoba (0.16) than those for Winnipeg (0.032) and Ontario (0.0056), per 1,000 population. The differential prevalence of predisposing health conditions including diabetes, pregnancy and morbid obesity, has received considerable attention as explicators of severe outcomes of H1N1 pandemic in rural and urban communities in Canada [2]. The high rates of hospitalization and ICU admission within these remote regions, could be linked to both transmissibility of the disease and to the prevalence of factors predisposing to more severe outcomes in infected individuals.

An important index of transmissibility for a communicable disease is the basic reproduction number ( $R_0$ ) that represents the number of secondary infections generated by a single infected case in an entirely susceptible population [3]. Early published literature for the transmissibility of pandemic H1N1 infection provides a range of 1.2–1.8 for  $R_0$  [4,5,6,7], mainly in large urban settings, suggesting that the novel H1N1 strain was less transmissible than the

1  
2  
3 1918-1919 pandemic virus for which  $R_0$  has been estimated in the range 1.8–3.0 [8]. However,  
4  
5  
6 early estimates may not apply in remote and isolated communities that have distinct  
7  
8  
9 demographic characteristics, as well as distinct environmental (built or natural) conditions. We  
10  
11 sought to evaluate differential transmissibility of H1N1 in five distinct population settings in  
12  
13  
14 Canada: a remote/isolated community in the Burntwood health region of northern Manitoba,  
15  
16 three remote/isolated communities in Nunavut, and compare them with the largest urban area  
17  
18 (i.e., the Winnipeg health region) in Manitoba. Communities in Nunavut as well as several  
19  
20 communities in northern Manitoba would be considered remote and/or isolated communities  
21  
22 [9] and many of these geographic areas have predominantly Aboriginal populations (e.g., 85%  
23  
24 of the Nunavut population and 76% of the northern Manitoba region self-identify as Aboriginal)  
25  
26  
27 [10].  
28  
29  
30

### 31 **Material and Methods**

32  
33 To estimate plausible ranges for  $R_0$ , we employed a discrete time epidemic model, and  
34  
35 fitted to infection curves inferred from collected data for laboratory-confirmed cases of H1N1  
36  
37 infection during the first wave of the 2009 pandemic. Details of data and estimation procedure  
38  
39 are described below.  
40  
41  
42  
43  
44

### 45 **Case Data**

46  
47 We obtained the daily number of laboratory-confirmed cases of pandemic H1N1  
48  
49 influenza (in which the cases were reported based on the earliest date of symptom onset, initial  
50  
51 care, specimen collection, hospital admission, or ICU admission) for the period of May 3 to  
52  
53 August 5, 2009, for each community under study. A laboratory-confirmed case was reported as  
54  
55  
56  
57  
58  
59  
60

an individual with ILI or severe respiratory illness who tested positive for pandemic H1N1 influenza A virus by real-time reverse-transcriptase PCR (RT-PCR) or viral culture. These data were collected and provided by Manitoba Health, and the Nunavut Department of Health and Social Services.

### **The Model**

We considered a homogeneous mixing structure for the model in which individuals are identified by their epidemiological status as susceptible ( $S$ ), exposed but not yet infectious ( $E$ ), Infectious ( $I$ ), and recovered ( $R$ ). Exposed state refers to the period of time following transmission of infection during which the newly infected person cannot transmit the disease and symptoms are absent before developing clinical disease. Assuming that the reduction in the number of susceptibles is small during the early stages of the outbreak (i.e.,  $S(t)/S_0 \approx 1$ , where  $S_0$  is the initial number of susceptibles) [11], the number of infections at time  $t$  is given by [12]

$$I(t) \approx I_0 e^{\frac{1}{2} \left[ \sqrt{4(R_0 - 1)\sigma\gamma + (\sigma + \gamma)^2} - (\sigma + \gamma) \right] t} \quad (1)$$

where  $\sigma$  and  $\gamma$  are the average duration of exposed and infectious stages,  $I_0$  is the initial number of infectious cases (in this case, the number of cases in datasets generated through sampling described below), and  $R_0$  is the basic reproduction number. The expression (1) describes the exponential growth of epidemic spread following disease outset. We estimated  $R_0$  by fitting  $I(t)$  to infection curves during the exponential phase of epidemic growth.

### Model Parameters

The values of exposed and infectious periods were taken from estimated ranges in the published literature specific to the 2009 pandemic, with a fixed exposed period of 1 day [13]. We sampled the duration of infectiousness from a log-normal distribution with the mean of 3.38 days [11]. Using a common heuristic, that the generation times can be estimated as the sum of the exposed period and half of the duration of infectiousness [14], leads to a mean generation times of 2.69 days. Considering a size-biased sampling approach, where primary cases with many secondary cases are assigned a greater weight [15], the mean of generation times includes an additional term given by variance multiplied by half of the duration of infectious period. This gives a slightly higher mean generation times of 2.78 days which lies within the estimated range for pandemic H1N1 [16,17,18].

### Sampling

To determine the variability in  $R_0$ , we generated 1000 datasets for case counts on each day through sampling from a Poisson distribution. We considered the absolute difference between the number of laboratory confirmed cases on day  $j$  and day  $j+1$  as the mean of distribution. To generate new datasets, we added (subtracted if the difference was negative) the sampled value to the number of reported cases on day  $j$  to obtain new cases on day  $j+1$ . This sampling approach captures a higher variability in the number of observed cases during the epidemic course and a smaller variability at the onset or towards the end of epidemic [19]. To create an infection curve for each dataset, first we sampled an infectious period for each case from a log-normal distribution with the scale parameter  $a = 1.192$  and shape parameter

$b = 0.05$  [11]. We assumed that the infectious period was initiated one day before the case was confirmed (reported date) [11,12]. This effectively means that every case was on the infection curve  $I(t)$  for its sampled duration of infectiousness (Figures 1 and 2).

### ***R<sub>0</sub> Estimation***

Since the reproduction number only reflects the growth rate during the early stages of the epidemic, estimating  $R_0$  is sensitive to the time period chosen for fitting the model to the data [20]. For a fit with very short timelines following the onset of the outbreak (establishment phase), the uncertainty in estimates of  $R_0$  will be high. On the other hand, fitting the model using data that extend beyond the epidemic peak, will result in underestimating  $R_0$ , through the influence of several factors, including widespread implementation of public health measures and an increase in herd immunity, which may in turn invalidate the assumption  $S(t) / S_0 \approx 1$ . In order to minimize these effects, we obtained the turning points of the outbreaks following the initial exponential growth phase, beyond which the epidemic will no longer have exponential growth. We performed fitting from the date at which the first laboratory confirmed case was identified, up to one day before the turning point for each infection curve, to ensure that  $R_0$  estimates reflect the initial growth phase of the outbreak. Turning point for each dataset was obtained through fitting the Richards model to the cumulative number of daily counts in each infection curve [21,22]. Assuming that  $K$  represents the cumulative number of daily cases for an infection curve  $I(t)$  (generated through sampling method described above), the first turning point  $t_m$  was obtained by solving the equation  $I(t_m) = K(1+c)^{1/c}$ , where  $c$  is the deviation parameter estimated using the method of least

squares through curve-fitting [23]. This equation holds at the inflection point for the solution of the Richards model. We then estimated  $R_0$  by fitting  $I(t)$  in equation (1) to the generated infection curves from the date of the first laboratory case until  $t_m - 1$ . The mean values and 95% confidence intervals were obtained from the  $R_0$  distributions generated through fitting procedure.

## Results

The infection curves generated for fitting are illustrated in Figures 1 and 2. The mean estimate of  $R_0$  for a northern community in Manitoba (Figure 1a) is 2.26 (95% CI: 1.57–3.75), which is higher than the estimate for Winnipeg health region with the mean value of 1.57 (95% CI: 1.35–1.87). We obtained considerably higher estimates for the mean values of  $R_0$  for other communities in the territory of Nunavut (Figures 1b,c,d): 3.91 (95% CI: 3.08–4.87); 2.03 (95% CI: 1.50–3.19); and 2.45 (95% CI: 1.68–3.44). Mean values of  $R_0$  stay above previous estimates for H1N1 transmission in larger communities and urban centres [4,5,6,7]. While estimated  $R_0$  ranges considerably overlap, outbreaks in Nunavut appear to have been driven by somewhat higher transmissibility that is comparable or higher than that of the 1918 pandemic [8]. We further estimated  $R_0$  by creating a single dataset for northern communities in Manitoba and Nunavut. The mean value of  $R_0$  was 2.21 (95% CI: 1.98–2.50), providing a significant difference (Wilcoxon signed-rank test:  $p < 0.001$ ) when compared with  $R_0$  estimates for the Winnipeg health region.

## Discussion

Determining the variability in transmissibility of a novel disease in populations with different demographics (e.g., age structure, household composition, and housing density) is crucial for identifying the within-community factors that have the greatest influence on disease spread and, (by changing the total number of infections), its severity. Our results suggest that more severe outcomes observed in the 2009 influenza A H1N1 pandemic in remote and isolated communities [2] may have been due to differential transmissibility of infection, resulting in more rapid epidemic spread and larger numbers of individuals affected at northern latitudes [24].

Estimates of transmissibility could play an important role in determining the most effective utilization of public health interventions, in particular when resources are scarce. It is important to note that  $R_0$  is effectively an *exponent* that determines both epidemic growth properties at the early stage of disease outset, the final size of an epidemic in the absence of interventions, and the fraction of individuals who need to be vaccinated to achieve herd immunity [25]. For example, the expected relative final size of an epidemic with an  $R_0$  of 2.7 is 25% larger in the absence of intervention than an epidemic with an  $R_0$  of 1.8; and to attain an immune herd (i.e., critical vaccination level:  $1-1/R_0$ ), the absolute fraction of the population vaccinated must be 19% higher in the population with the higher  $R_0$ . This has important public health implications for vaccination programs and suggests that transmissibility is an important consideration in prioritizing the allocation of limited health resources.

The mechanisms underlying the differential transmissibility of a pathogen in these Canadian communities are unclear, but could be related to the effectiveness of available disease control programs, environmental factors including the prevalence of low quality housing [26], exposure to indoor air pollutants, lack of access to clean water, and also to differences in demographic characteristics, crowding, and mixing patterns. For example, the average number of persons per household in the northern Manitoba region is 3.6, which is 44% greater than the mean size of 2.5 persons per household in Winnipeg as the largest urban centre in the same province [27,28]. The average number of people per household in Nunavut is 3.8, which is higher than both northern Manitoba and Winnipeg [10]; this may therefore account for a higher rate of secondary household transmission, which is known as a major route for the spread of influenza infection in the wider community [29,30,31]. In addition, age has been recognized as an important parameter for the spread of disease with higher rates of infectious contacts among schoolchildren and younger adults. There are also differences in the age profiles of the populations studied here with other urban centres. For example, the average age in the northern Manitoba region is 24 and in Nunavut is 23 [10], which is approximately 15-16 years younger than the average age (38.7) in Winnipeg [27,28]. In Nunavut, only 2.7% of the population is greater than 65 years of age and 34% of the population is less than 15 years of age [10]. Although older age has been associated with a higher risk of severe outcomes during seasonal influenza epidemics, pandemics (e.g., 1918, 1957) are generally characterized by high rates of morbidity and mortality among younger adults [32,33], as has also been documented for the 2009 H1N1 pandemic [34]. Moreover, serological studies have shown the existence of cross-reactive antibody responses for individuals older than 50 years of age due to prior

1  
2  
3 exposure to similar viruses [35], which may reflect a reduced likelihood of H1N1 infection in  
4  
5  
6 older populations. As was observed in other geographic regions [36], in Manitoba the 2009  
7  
8  
9 pandemic predominantly affected young adults and children in both spring and fall waves  
10  
11 (Figure 3).  
12

13  
14 In populations with low mean age (such as Nunavut), the buffering effect of pre-existing  
15  
16 immunity in older individuals is less pronounced, which may contribute to higher  
17  
18 transmissibility of the virus. In remote and isolated communities in Canada, climate, healthcare  
19  
20 capacity in the community, socioeconomic status, health status, presence of vulnerable groups  
21  
22 (e.g., children < 5 years of age, immunocompromised, and pregnant women), limited numbers  
23  
24 of healthcare workers in the community, equipment and facilities, medical transportation and  
25  
26 other critical infrastructure such as housing also play a role in determining differential epidemic  
27  
28 impact [37].  
29  
30  
31  
32  
33

34  
35 The model employed in this study is subject to limitations, including the simplifying  
36  
37 assumption of homogeneity in the population interactions. Some of the limitations are imposed  
38  
39 by the lack of specific data, which precludes the use of more complex models with network  
40  
41 structure or age-stratified populations. The simple model structure does not elucidate the  
42  
43 specific mechanisms driving increased transmissibility in these communities. However,  
44  
45 empirical evidence to support the observation of increased transmissibility in these  
46  
47 communities clearly demonstrates the need for ongoing research in order to identify the  
48  
49 specific mechanisms. Due to uncertainties in the level of pre-existing immunity and its  
50  
51 distribution in different age-segments of the population, we did not include the effect of  
52  
53 immune responses in our model. However, considering prior immunity [38] we would expect to  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 estimate greater values for  $R_0$  compared to when the entire population is assumed to be  
4  
5 susceptible. Finally, our model considers these communities without considering travel or  
6  
7 interactions with other population settings in the same region. It is possible that some influenza  
8  
9 cases were undiagnosed and thus not captured in surveillance data; this would lead us to  
10  
11 underestimate the transmissibility of the virus, making our estimates “lower bound” estimates.  
12  
13 We would expect underreporting to be less likely in the first wave of the pandemic (the time  
14  
15 period that we examined) than the second wave, as individuals with influenza-like illness  
16  
17 symptoms were encouraged to seek medical care, especially in remote and isolated  
18  
19 communities. In the absence of data for the true burden of the disease, we used laboratory  
20  
21 confirmed case counts, which may be subject to biases due to differential rates of testing  
22  
23 between different age groups, different geographic regions, and over time. However, it is  
24  
25 difficult to assess the magnitude and direction of such biases. Data available for this study did  
26  
27 not provide any relevant information on other potential confounders that could be included in  
28  
29 our estimation model. Despite these limitations, our results suggest that there is indeed a  
30  
31 considerable difference between the reproduction numbers of H1N1 outbreaks in remote and  
32  
33 isolated communities and urban centers. Further investigation is required to explore the  
34  
35 underlying mechanistic reasons for this differential transmissibility, which could determine  
36  
37 population specific factors that should be integrated into the process of public health decision  
38  
39 making for future planning, in the face of an emerging infectious disease.
