ABSTRACT

Objective: To estimate the willingness to pay (WTP) per quality-adjusted life year (QALY) value for life-saving treatments and to determine factors affecting the WTP per QALY value.

Design: A cross-sectional survey with multistage sampling and face-to-face interviews.

Setting: General population in the southern part of Thailand.

Participants: A total of 600 individuals were included in the study. Only 554 (92.3%) responses were usable for data analyses.

Outcome measure: Participants were asked for the maximum amount of WTP value for life-saving treatments by an open-ended question. EQ-5D-3L and visual analogue scale (VAS) were used to estimate additional QALY.

Results: The amount of WTP values varied from 0 to 720 000 Baht/year (approximately 32 Baht=US\$1). The averages of additional QALY obtained from VAS and EQ-5D-3L were only slightly different (0.872 and 0.853, respectively). The averages of WTP per QALY obtained from VAS and EQ-5D-3L were 244720 and 243120 Baht/QALY, respectively. As compared to male participants, female participants were more likely to pay less for an additional QALY ($p=0.007$). In addition, participants with higher household incomes tended to have higher WTP per QALY values ($p<0.001$).

Conclusions: Our study added another WTP per QALY value specifically for life-saving treatments, which would complement the current cost-effectiveness threshold used in Thailand and optimise patient access to innovative treatments or technologies.

Strengths and limitations of this study

- This study used legitimate hypothetical health scenarios, for example, targeted health state, along with a rescaling utility measure, to improve the method for examining WTP per QALY value for life-saving treatments in Thailand.
- The study provided evidence that a simple approach might work for examining the WTP per QALY value for setting cost-effectiveness (CE) threshold for life-saving technologies. It supports the concept of using a flexible CE threshold, which indicates that a single CE threshold for all technologies is not appropriate.
- Study results can be generalised to only a specific Thai population.

which cover almost 90% of overall population.⁴ Therefore, the government needs to efficiently allocate resources.^{5 6}

It has been widely accepted that economic evaluation, for example, cost-effectiveness analysis (CEA) and cost-utility analysis (CUA), is an important decision-making tool for healthcare resource allocation.⁷ Economic evaluation compares costs and benefits between competing technologies as incremental cost-effectiveness ratio (ICER) or incremental cost-utility ratio (ICUR).^{8 9} A common measure of trading off between costs and benefits is incremental cost per quality-adjusted life year (QALY) gained.¹⁰ In general, as long as a technology has additional costs for additional benefits, it requires a cost-effectiveness threshold (CE threshold) to determine whether it is cost-effective or not.^{11–13}

CE thresholds have been stated implicitly or explicitly and vary across jurisdictions, for example, they are US\$50 000 per QALY in the USA,¹⁴ \$C20 000–100 000 per QALY in Canada¹⁵ and £20 000–30 000 per QALY in the UK.¹⁶ There is no single standard method for valuing CE threshold. It could be derived from several methods including WHO

CrossMark

INTRODUCTION

Increasing health expenditures has been an important problem around the globe.^{1 2} In Thailand, total health expenditures were 367 767 million Baht in 2008, an increase from 127 655 million Baht in 1994. It was approximately 4% of the country's gross domestic product (GDP) and rose due to various reasons, for example, innovations.³ The Thai government is responsible for two of three major health insurance schemes,

recommendations, a human capital approach, expert opinion and willingness to pay (WTP).^{17–19} However, there have been studies examining WTP per QALY and using it to verify the CE threshold value used in each individual country, for example, the USA, Denmark, Australia, South Korea, Taiwan and Thailand.^{20–33} A stated preference method, contingent valuation (CV), has been used to elicit WTP per QALY in several studies because it can generate hypothetical scenarios based on diseases or health status. For example, King *et al*²⁶ used a visual analogue scale (VAS), standard gamble (SG) and time trade-off (TTO) for utility measurement, and used an iterative closed-ended bidding method to determine WTP per QALY for moving from current health state to perfect health state, and Shiroya *et al*²³ used bid values in double-bound dichotomous choice to determine WTP per QALY for an additional 1 year of survival with perfect health status.

In Thailand, the CE threshold was previously implicitly set as one to three times GDP per capita, based on WHO recommendations.¹⁹ Recently, the commissioners of health technology assessment recommended <1.2 times the per capita gross national income (GNI) (160 000 Baht) for the CE threshold.³⁴ There are two studies examining WTP per QALY to verify CE threshold in the country. Thavorncharoensap *et al*²⁴ estimated WTP per QALY in 2008 by using a bidding game technique for WTP measures and using TTO and VAS for utility measures in moving from various health conditions, including blindness, paralysis and allergy for 5 years as hypothetical scenarios to current health state. Later, Thavorncharoensap *et al*³⁵ used a double-bounded dichotomous choice method followed by open-ended questions to examine WTP for moving from three major health states including treatment scenario, life extension and life-saving situation, to either full health or an extension of life for various durations, which produced 0.2 and 0.4 QALY gained. The study results confirmed the legitimacy of the currently used CE threshold in the country.

However, according to the current CE threshold, a number of technologies and programmes are not cost-effective. Some cases were controversial since they were generally cost-effective in other countries. For instance, once-in-a-lifetime population-based mammographic screening for women aged either 40–49 or 50–59 years was determined as not cost-effective or did not have good value for money in Thailand.³⁶ Similarly, in the case of new technologies or treatments for life-threatening diseases, since they are potentially not cost-effective, patients would have limited access to them. It would be interesting to specifically examine the WTP per QALY value for these types of disease. Therefore, the objectives of this study were to estimate WTP per QALY value for life-saving treatments and to determine factors affecting the WTP per QALY value. This study was part of a larger project that used another method to elicit WTP per QALY.

METHODS

Questionnaire development

We used a questionnaire survey as a tool to collect data in this study. It was composed of three parts, including utility measurement, WTP measurement and demographic questions. Since EQ-5D-3L and VAS are easily understood and administered, we used them to measure utility or an additional QALY that an individual gained from moving between two health scenarios, which were a health state with life-threatening disease and current health state. The EQ-5D-3L was composed of five dimensions: mobility, self-care, usual activities, pain or discomfort and anxiety or depression. Each dimension has three levels including no problems, some problems and extreme problems.^{37–38} Participants were asked to choose levels of all dimensions. For VAS, we used a 0–100 unit ‘thermometer-type’ scale, where 0 and 100 were labelled ‘dead’ and ‘perfect health’, respectively.³⁷ Participants were asked to evaluate health states on three thermometer-type scales, consisting of perfect health state, dead state and current health state, consecutively. They marked only one point at first and second scales as warm-up exercises. On the third scale, we asked them to mark the three points of perfect health state, dead state and current health state.

We used a single question, ‘Please imagine that you have had a life-threatening disease for 1 year. If you do not receive treatment you will die today. On the other hand, there is a treatment that can help you get back to your current health state but you can only live for one more year (in the current health state) and then die. What is the maximum value would you be willing to pay per month for that treatment for 1 year?’, to determine WTP. In addition, the trained interviewers asked respondents to review the scenario and question to check their understanding, and emphasised that the amount of payment should be under that they would be able to pay. If they did not want to pay, we asked them for their reasons. In the questionnaire, we also asked for participants’ gender, residential area, age, education, health scheme, marital status, number of family members, individual income, household income and diseases that they currently had.

We asked three experts to review the questionnaire to check content validity and we made a revision accordingly. To ensure the validity of the questionnaire, we carried out three rounds of interviews with 10 conveniently sampled participants each and adjusted the questionnaire. We then piloted it with 30 participants residing in Songkhla province and found that they clearly understood the questions, and could imagine the hypothetical scenarios included in the questionnaire.

Data collection

The National Statistical Office of Thailand calculated sample size and selected respondents representing the population of southern Thailand targeted for our study, where we could reach out using limited resources.

All provinces were classified by average household income and a stratified multistage cluster random sampling technique was used to identify areas and households. We finally needed to conduct face-to-face interviews with a total of 600 individuals residing in three provinces including Surat Thani, Pattalung and Satun. The data collection period in December 2013 and ended in February 2014. We had seven trained interviewers in this study. After the interviews, we provided a token of appreciation to the interviewers as well as to participants.

Data analysis

All analyses were performed using SPSS V.18.0 for Windows (Chicago, Illinois, USA). We descriptively analysed demographic data. We used EQ-5D-Thai tariff to calculate utility scores of all current health states.³⁸ The marked points of the third thermometer-type scale were used to calculate the current health state utility of participants. Some respondents did not correctly mark the perfect health state and death state on the scale at 100 and 0, respectively. Therefore, rescaling was necessary in calculating utility of current health state depending on each individual.³⁹ The rescaling formula is shown below,

$$\text{VAS}_{\text{current health state-rescaled}} = \frac{\text{VAS}_{\text{current health state-raw}} - \text{Death}_{\text{raw}}}{\text{'11111'}_{\text{raw}} - \text{Death}_{\text{raw}}}$$

where $\text{VAS}_{\text{current health state-rescaled}}$ is the utility of rescaled current health state, $\text{VAS}_{\text{current health state-raw}}$ is the score of current health state, $\text{Death}_{\text{raw}}$ is the score of death and '11111'_{\text{raw}} is the score of perfect health state.

We calculated WTP per QALY value from the ratio of WTP value for saving their lives from death due to life-threatening disease to current health states and the additional QALY. All data of unwillingness to pay values were transformed to zero and included in calculation. The additional QALY was derived from the difference of utilities between death due to life-threatening disease ($u=0.000$) and current health state of each individual. Specifically, we used the following formula to calculate WTP per QALY for each respondent.

$$\text{WTP per QALY} = \frac{12 \times \text{WTP/month}}{U_{\text{current health state}} - U_{\text{death}}}$$

where WTP per QALY is the WTP per QALY value, WTP/month is the amount of WTP (Baht) per month, $U_{\text{current health state}}$ is the utility of current health state and U_{death} is the utility of death due to life-threatening disease. We calculated the average WTP per QALY values from each individual WTP per QALY.

Finally, we performed multiple linear regression analysis to examine the factors affecting WTP per QALY values. We transformed the WTP per QALY values derived from the rescaled VAS to log scale and used

them as dependent variables, and used demographic variables as independent variables, in this analysis.

RESULTS

Demographic data

A total of 554 (92.3%) responses were usable for data analyses. While 38 (6.3%) participants did not understand how to mark on VAS for the three health states, 5 (0.8%) participants could not imagine the hypothetical scenarios and 3 (0.5%) participants could not indicate the maximum payment for the treatment of life-threatening disease. Table 1 shows the characteristics of participants. The average age of participants was 41.4 years. The number of female participants was a little more than male participants. The majority (62.8%) lived in rural areas. Most participants had a secondary school degree (39%) and were married (74.2%). The averages of individual income and household income were approximately 13 000 and 30 000 Baht/month, respectively.

WTP and WTP per QALY

Table 2 shows WTP values, additional QALYs and WTP per QALY values. A total of 534 participants were willing to pay for life-saving treatments. Twenty (3.6%) participants were unwilling to pay. These included 13

participants who could not afford to and seven participants who believed the Thai government should support the cost of treatments. We found that WTP values for life-saving treatments varied from 0 to 720 000 Baht/year (approximately 32 Baht=US\$1). The averages of additional QALY obtained by VAS and EQ-5D-3L were only slightly different (0.872 and 0.853, respectively) and the averages of WTP per QALY from both utility measurement methods were also similar (244 720 and 243 120 Baht/QALY, respectively).

Factors affecting WTP per QALY values

WTP per QALY values had positively skewed distribution and were transformed to log (WTP per QALY). Before

analysis, we excluded responses from three participants who had outlier WTP per QALY values since they might lead to biased results. Table 3 shows the results of multiple regression analysis for factors affecting the WTP per QALY values. Multiple linear regression analysis built a significant model ($F=8.432$, $R^2=0.121$, degree of freedom=8, $p<0.001$). Only gender and household income were statistically significant factors associated with the WTP per QALY values. As compared to male participants, female participants significantly had lower WTP per QALY values ($p=0.007$). In addition, participants with higher household incomes tended to have higher WTP per QALY values ($p<0.001$).

DISCUSSION

The study results showed that participants were willing to pay approximately 240 000 Baht for an additional QALY in cases of saving their lives from death due to life-threatening disease to current health states. This amount was 1.42 times Thailand GDP per capita, or 1.80 times GNI per capita, which was still lower than the highest CE threshold recommended by the WHO (three GDP per capita), and 1.50 times the implicit CE threshold (160 000 Baht/QALY or 1.2 times of GNI per capita) currently used in Thailand.³⁴ Interestingly, the WTP per QALY values derived from this study were in line with WTP per QALY for unilateral blindness treatment, but lower than WTP per QALY for a life-saving condition, which were derived from two previous studies in the country (285 000 and 334 045 Baht/QALY, respectively).^{24 35}

Different concepts and methods might be main reasons for the discrepancies between these WTP per QALY values. For instance, CE threshold recommended by the WHO and CE threshold currently used in Thailand were both based on income, while the results from two previous studies in the country were based on preference.^{24 35} However, the diseases used among these studies were also different. The first study examined the WTP for three diseases, including unilateral/bilateral blindness, paraplegia/quadruplegia and mild/moderate allergies, while another study used three situations, treatment, life extension and life saving, to determine the WTP per QALY values.^{24 35} In our study, we only used a life-threatening disease. In addition, outcomes of treatment were set differently. For instance, one of the previous studies asked participants for their WTP for a treatment that could return them from blindness to current health state,²⁴ while another study asked participants for their WTP for a treatment that could bring them back from a serious disease to full health.³⁵ However, the participants in this study considered their WTP for a treatment that could move them back from death due to a non-specific serious disease to their current health state. Also, generally asking participants to imagine recovery from a disease to current health state should be more legitimate than moving from life-threatening disease back to full health, as used in a previous study.³⁵ Therefore, although this study showed that the WTP per QALY derived from death due to a serious disease moving to the current health states for 1 year was lower than the WTP per QALY derived from immediate death due to a serious disease moving to the full health state for 2 months (334 045 Baht/QALY), as used in one of the previous studies,³⁵ these types of study results might not be a proper comparison.

Another reason for the different WTP per QALY values could be from the different WTP elicitation methods used among these preference-based studies. Although the advantages of using an open-ended question in this study were that it was easier to understand and it required a short time for interviews, one of the disadvantages was that it was difficult to answer, as compared to other techniques such as closed-end or bidding, and it could usually lead to low response rates.⁴⁰ Therefore, the open-ended question could be the reason explaining lower WTP per QALY in this study, as compared to other WTP per QALY values derived from life saving and life extension used in previous study.^{24 35}

We also found that the amount of payment was approximately 70% of household income. This result was consistent with the results from previous studies. In general, respondents would express maximum WTP for life saving or life extension.^{41–43} For instance, Pennington *et al*⁴³ found that deriving a WTP for a QALY from coma and terminal scenarios generated higher values than those from other scenarios. One of the reasons would be that this type of scenario is likely

to depress marginal utility of income, and money might be worthless to individuals under these circumstances. Therefore, it was possible that respondents in this study fully recognised life-saving treatments and might have thought of other financial resources, for example, household income and bank deposits, and selling their properties, to pay for the treatments.

On the contrary, 20 respondents in this study were unwilling to pay for saving their lives in the hypothetical scenario. We found that their household incomes varied widely from 5000 to 110 000 Baht/month. Therefore, the reasons for their unwillingness to pay could be that they could not really afford to or they intentionally did not want to pay if they were in that state of health. Also, from the question estimating WTP in this study, the average WTP was derived from only 1 year of treatment. WTP might change in different durations.²³ Therefore, it limits the generalisability of the results.

Interestingly, all preference-based study results, including this study, revealed that the WTP per QALY was higher than the current CE threshold used in Thailand. Although this was important information, and reflected public opinion, it was not meant to be the best justification for any single ceiling CE threshold. Instead, the results supported using flexible CE thresholds for different health conditions.^{31 44 45} In fact, some countries have already adopted flexible CE thresholds, for example, the Netherland has a specific CE threshold for treatments of life-threatening diseases.⁴⁶

Another intuitive result was that the household income of participants was a statistically significant factor affecting the WTP per QALY value. Participants who had higher incomes were willing to pay more for an additional QALY. This result was consistent with the findings in a previous study.²⁴ It was also consistent with the data that we found in 12 of 20 participants who expressed unwillingness to pay for treatments of life-threatening diseases, they had low income. Although education level was not a significant factor in this study, as it was in a previous study, participants with higher education levels tended to have higher WTP per QALY. Moreover, male participants were willing to pay more than female participants, 49 713 Baht/QALY on average. This result was consistent with a previous study's result.²⁴

The results of this study added two important elements to the WTP per QALY literature for Thailand. First, they revealed the WTP per QALY for moving away from a health state with life-threatening disease to current health state, instead of full health, as in the most recent study, which is not usually the case in reality. Second, this study showed evidence that using a simple hypothetical question to determine the WTP per QALY might work in the same manner as using sophisticated utility and WTP measures, as seen in previous studies, since the WTP per QALY was not greatly different as long as the initial and ended health states were the same or similar. Those investigators used a lot of resources to determine the WTP per QALY, and were always

concerned about the participants' comprehension of included scenarios. If there is more evidence that using simple hypothetical scenarios works well, it will allow more opportunity for researchers or policymakers to use different CE thresholds for economic evaluation of different technologies.

There were two main limitations in this study. First, the participants did not represent the entire Thai population, which might include different socioeconomic characteristics. We needed to carefully generalise the results. For instance, the average household income of our participants and that in the general Thai population in 2013 were different (approximately 30 000 and 19 000 Baht/month, respectively).⁴⁷ Second, we estimated the WTP per QALY value using only one life-threatening disease scenario. The WTP per QALY in this study should not be used in other situations. Instead, valuing WTP per QALY from different hypothetical scenarios should be estimated in future studies.

CONCLUSIONS

Health technology assessment is the norm for allocation of healthcare resources in Thailand. CE threshold is essential when upcoming competing technologies have greater effectiveness and higher cost than present technologies. It also has an impact on patient access to new technologies. Our study added another WTP per QALY value specifically for life-saving treatments, complementing the current CE threshold used in the country and helping to optimise patient access to treatments or technologies.
