ABSTRACT

Objective: Both environmental and genetic factors play important roles in the development of metabolic syndrome (MetS). Studies about its associated factors and genetic contribution in African Americans (AA) are sparse. Our aim was to report the prevalence, associated factors and heritability estimates of MetS and its components in AA men and women.

Participants and setting: Data of this cross-sectional study come from a large community-based Jackson Heart Study (JHS). We analysed a total of 5227 participants, of whom 1636 from 281 families were part of a family study subset of JHS.

Methods: Participants were classified as having MetS according to the Adult Treatment Panel III criteria. Multiple logistic regression analysis was performed to isolate independently associated factors of MetS (n=5227). Heritability was estimated from the family study subset using variance component methods (n=1636).

Results: About 27% of men and 40% of women had MetS. For men, associated factors with having MetS were older age, lower physical activity, higher body mass index, and higher homocysteine and adiponectin levels ($p<0.05$ for all). For women, in addition to all these, lower education, current smoking and higher stress were also significant ($p<0.05$ for all). After adjusting for covariates, the heritability of MetS was 32% ($p<0.001$). Heritability ranged from 14 to 45% among its individual components. Relatively higher heritability was estimated for waist circumference (45%), high density lipoprotein-cholesterol (43%) and triglycerides (42%). Heritability of systolic blood pressure (BP), diastolic BP and fasting blood glucose was 16%, 15% and 14%, respectively.

Conclusions: Stress and low education were associated with having MetS in AA women, but not in men. Higher heritability estimates for lipids and waist circumference support the hypothesis of lipid metabolism playing a central role in the development of MetS and encourage additional efforts to identify the underlying susceptibility genes for this syndrome in AA.

Strengths and limitations of this study

- The African American community disproportionately suffers from metabolic syndrome, but relatively little is known about the genetic contribution and the environmental influence of this syndrome among African Americans.
- Using the data from a large community-based Jackson Heart study, this study showed a high prevalence of metabolic syndrome, and reported the associated factors and heritability estimates of metabolic syndrome and its components in African Americans.
- We are not aware of any published data that explored these issues among African Americans from such a big setting. The large sample size also provided a more reliable statistical ground to detect heritability estimates than nuclear families, twin pair data or sib-pair data.
- Potential limitations of this study included the cross-sectional observational design, which could only confirm the associations of the factors with metabolic syndrome, but not the causality, and the absence of information on shared environmental factors like childhood environment and neighbourhood factors, which might slightly overestimate the heritability results.
- This study encourages additional efforts to identify the underlying susceptibility genes for metabolic syndrome among African Americans.

BACKGROUND

Metabolic syndrome (MetS) is a clustering of different interrelated cardiometabolic risk factors including obesity, elevated blood pressure (BP), dyslipidemia and impaired fasting plasma glucose (IFG). These risk factors often occur together and increase cardiovascular disease (CVD) deaths almost by three-fold to fourfold.^{1 2} Since MetS is the

combined effect of more than one risk factor, its aetiology is complex. Factors like lifestyle, gender, ethnicity, socioeconomic status, psychosocial factors and some inflammatory markers play key roles in the pathogenesis of MetS.^{1–3} Findings also suggest that MetS clusters in families^{4–8} and has reasonable heritability, which is defined as the proportion of phenotypic variance in a trait that is attributable to the additive effects of genes.^{9–17} Thus, the interplay of environmental and genetic factors makes MetS a multifactorial disorder.

Though the pathogenesis, diagnosis and the treatment of MetS remain complex because of its multifactorial nature, the construct MetS is an important risk-assessment method for early detection and early intervention of CVD. In spite of the steady decline in CVD mortality during recent decades, CVD is still the leading cause of death in all Americans, and is highly prevalent in persons of African ancestry.¹⁸ It is important to note that the majority of studies that explored the associated factors and quantified the heritability of MetS almost exclusively involved Caucasians.^{10–14 19} Relatively little is known about these issues among the adult African American (AA) population.^{15–17} Using the Jackson Heart Study (JHS) data, the objective of this cross-sectional study was to report the prevalence, risk factors and heritability estimates of MetS and its components in AA men and women.

METHODS

Data source

The data for this analysis come from a large community-based JHS, which comprises 5301 adult AA enrolled between September 2000 and March 2004 and residing in Jackson, Mississippi metropolitan area.²⁰ About 24% of the 5301 adult AA participated in the JHS family study component.²¹ The family study component of JHS contained first degree (parent-offspring and siblings), second degree (grandparent-grandchild, avuncular, half-siblings) and third degree or more distant (great grandparent-grandchild, grand avuncular, half avuncular, first cousins, half first cousins, second cousins) family members. The JHS was approved by the University of Mississippi Medical Center Institutional Review Board, and the participants gave written informed consent. Details of the study design and data collection methods are described elsewhere.^{21 22} The current study data were obtained from the baseline clinic visit during 2000–2004. After excluding 74 participants who did not have information on their MetS status, the current analysis had a total of 5227 participants, of whom 1636 from 281 families contributed to the heritability analyses.

Measures

We collected information on participant's waist circumference (WC), systolic BP (SBP) and diastolic BP (DBP), fasting plasma glucose (FPG), fasting triglyceride and plasma high-density lipoprotein cholesterol (HDL-C).

Two measures of the waist at the level of the umbilicus and in the upright position were averaged to calculate WC. Sitting BP was measured twice at 5 min intervals with a standardised Hawksley random-zero sphygmomanometer, and the average of two measurements was used. Fasting blood samples were collected according to standardised protocols, and the assessments of FPG and lipids were processed at the Central Laboratory, University of Minnesota.²³ Respondents were asked about their medication usage for hypertension, diabetes mellitus and high lipid levels. Individuals were classified as having MetS if they had at least three of the following five components: (1) large WC or abdominal obesity (>102 cm for men and >88 cm for women); (2) hypertriglyceridaemia (fasting plasma triglyceride concentration ≥ 150 mg/dL or on drug treatment); (3) low HDL-C levels (<40 mg/dL for men and <50 mg/dL in women or on drug treatment); (4) elevated BP (≥ 130 mm Hg SBP or ≥ 85 mm Hg DBP or on drug treatment); or (5) IFG (≥ 110 mg/dL or on drug treatment).^{24 25}

Data about socio-demographic (age, sex and education), psychosocial (stress) and lifestyle (physical activity, smoking status and alcohol consumption) variables were also collected. Age was classified as: 20–39, 40–59, 60–79 and 80 years and above. Education status was self-reported and was divided into three categories (less than high school, high school/some college and college/associate degree or higher, where less than high school was the referent). Stress level was obtained from The Global Perceived Stress Scale, an 8-item questionnaire that measures the severity of chronic stress experienced over a prior period of 12 months.²⁶ The physical activity index composite score was calculated as the sum of four different domains of physical activity: active living, work, home and garden, and sport and exercise indices.²⁷ Smoking status was classified as never (referent), current and former. Alcohol consumption status was defined as 'yes' if the participants currently consumed alcoholic beverages and 'no' (referent) if they had stopped drinking for more than a year, or if they never consumed alcohol. Information on clinical factors like body mass index BMI (weight in kg divided by height in meter square), C reactive protein or CRP (mg/dL), serum adiponectin (mg/dL) and serum homocysteine ($\mu\text{mol/L}$) was also obtained.²³

Analysis

Data from the full cohort ($n=5227$) were used to explore the risk factors of MetS. Sociodemographic, psychosocial, lifestyle and clinical characteristics of participants were compared by gender and MetS status using the χ^2 or independent t test. The primary outcome measure for this analysis was the presence of MetS, evaluated as a dichotomous variable. Logistic regression analysis was used to examine the association between each independent variable (age, education level, stress level, physical activity score, smoking status, alcohol consumption status, BMI, CRP, fasting total cholesterol, serum

concentration of adiponectin and serum homocysteine) and the outcome of MetS. A multiple logistic regression model was fitted including all variables to isolate the statistically significant predictors of MetS. The regression analysis was conducted using SAS software, V.9.3.²⁸

Heritability analysis

After checking the pedigree data for inconsistencies, a total of 1636 individuals from 281 families were analysed to calculate the heritability estimates by variance component methods using the SOLAR (Sequential Oligogenic Linkage Analysis Routines) software package to quantify the proportion of the variance in MetS and in its individual components that was attributable to the additive effects of genes.²⁹ We estimated the heritabilities of individual MetS components (treated as continuous variable) including WC, SBP, DBP, FPG, fasting triglyceride and plasma HDL-C with adjustment for age, education level, physical activity index composite score, smoking status, alcohol consumption status and respective medication usage. Log transformed values of FPG and triglycerides

were used due to deviation from the normal distribution. Heritabilities were calculated using a standard quantitative genetic variance-components model implemented in SOLAR.²⁹ This approach uses the maximum-likelihood estimation to a mixed-effects model that incorporates fixed covariate effects, additive genetic effects and residual error. The heritability of MetS (discrete variable) was analysed by a threshold model in SOLAR. The method assumed that an individual belonged to a specific affected status if an underlying genetically determined risk exceeded a certain threshold.³⁰

For all the analyses, a significance level set at $p < 0.05$ was used.

RESULTS

Table 1 presents the characteristics of JHS participants. Of the 5227 individuals, 1909 (36.52%, mean age 53.93 years and standard deviation or SD=12.93) were men and 3318 (63.48%, mean age 55.30±12.76) were women. Education levels were similar for men and

¶¶Metabolic syndrome defined as having at least three of the following five components: (1) abdominal obesity; (2) hypertriglyceridaemia; (3) low HDL cholesterol levels; (4) elevated blood; (5) impaired fasting glucose.

HDL-C, high-density lipoprotein cholesterol.

women. About 40% of men and women had college level education or beyond. A clear gender difference, however, was found for alcohol use and smoking, with women being far less likely than men to consume alcohol and smoke cigarettes ($p<0.001$). Women reported greater levels of stress, but lower levels of physical activity than men ($p<0.001$). Women also had higher BMI, CRP and adiponectin levels but lower homocysteine levels than men ($p<0.001$ for all). **Table 1** also shows the prevalence of MetS and its individual components among the JHS participants. About 27.34% of the men and 38.94% of the women had MetS ($p<0.001$). In terms of individual components, women had higher abdominal obesity (75.70% vs 41.03%, $p<0.001$) and IFG (22.45% vs 19.64%, $p<0.001$), but lower hypertriglyceridaemia (13.23% vs 18.39%, $p<0.001$) than men.

Table 2 shows the descriptive characteristics of participants by MetS status. Those who had MetS were older, less educated, less likely to smoke, less likely to consume alcohol and less physically active ($p<0.001$ for all). They also had higher BMI, CRP and homocysteine levels but a lower adiponectin concentration ($p<0.001$ for all). The unadjusted and the adjusted relationships of MetS with these features are displayed in **table 3**. After adjustment, older age remained significant for both men and women. Notably, the trend of having MetS with increasing age was clearer for women than for men. Education was only significant for women but not for men. Women who went to high school had 24% (adjusted odds ratio

or AOR: 0.76; 95% confidence interval or CI: 0.59 to 0.97) decreased odds of having MetS compared to those who had the lowest education level. Like education, higher stress level was also a significant factor for women only (AOR: 1.02; 95% CI: 1.01 to 1.04). Physical activity decreased the odds of having MetS for both sexes, but alcohol consumption was associated with 26% decreased odds (AOR: 0.74; 95% CI: 0.61 to 0.90) of MetS for women only. Relationship between smoking and MetS was different for men and women. While current smoking only predicted women's MetS (AOR: 1.43; 95% CI: 1.07 to 1.91), former smoking had a significant association with men's MetS (AOR: 1.54; 95% CI: 1.14 to 2.08). Biomedical risk factors such as increased BMI (AOR: 1.18; 95% CI: 1.15 to 1.21 for men and AOR: 1.08; 95% CI: 1.07 to 1.10 for women), increased serum homocysteine (AOR: 1.05; 95% CI: 1.02 to 1.09 for men and AOR: 1.06; 95% CI: 1.03 to 1.09 for women) and decreased serum adiponectin (AOR: 0.90; 95% CI: 0.85 to 0.95 for men and AOR: 0.90; 95% CI: 0.87 to 0.92 for women) were associated with increased odds of having MetS for both sexes.

Table 4 illustrates the heritability estimates along with the proportion of variation explained by covariates (σ_e^2) of MetS and its individual component in the family study subset ($n=1636$). All components of MetS were significantly correlated with each other except for the pairs of BP and HDL-C and BP and fasting glucose (results not shown in table). After accounting for the covariates (except medication), the heritability of MetS

σ_e^2 : 22%) were at the lower end and similar to the estimate of FPG. Conversely, heritability of triglyceride (42%, $p < 0.001$, σ_e^2 : 10%) and HDL-C (43%, $p < 0.001$, σ_e^2 : 11%) was relatively high and similar to the heritability of WC.

DISCUSSION

We provide here the epidemiological and heritability data about MetS and its related traits according to ATP III criteria among AA. Overall, in our study sample, the prevalence of MetS was higher among women than among men. Factors independently associated with having MetS for men were older age, lower physical activity level, higher BMI, higher level of homocysteine and lower level of adiponectin. For women, in addition to older age, lower physical activity level, higher BMI, higher level of homocysteine and lower level of adiponectin, low education, higher stress, current smoking and alcohol consumption were also significant. The heritability of MetS was 32% and among its individual components, heritability ranged from 14% for FPG to 45% for WC.

The prevalence of MetS that we found (38.94% of women and 27.34% of men) was almost identical to a recent estimate from a National Survey, which reported that 38.2% of AA women and 25.5% of AA men had MetS.¹ A higher prevalence of MetS in women than in men has been reported in several other Asian and Eastern European countries, as well as among Hispanics and Native Americans.^{1 31–33} However, it is opposite for US Caucasians with a higher prevalence in men.¹ This, together with our finding, suggests the possibility of an increased risk of MetS for women belonging to an economically disadvantaged or minority population group. The unfavourable condition of women was also evident from our multivariate analysis, where we found lower education and stress to be significantly related to MetS for women, but not for men. While social class and education are typically inversely related to different cardiometabolic risk factors regardless of gender in the industrialised society,^{34–36} in our study this was true only for women, indicating an adverse social environment of our women participants.

Literature has indicated active smoking to be associated with development of MetS.^{37 38} We, however, found active smoking to be associated with women's MetS only. The lack of association between current smoking and MetS among men in our study can be partly attributed to the much discussed inverse association between active smoking and obesity, as the smoking prevalence was higher and abdominal obesity was relatively lower in the men than women in our analysis.³⁹ Further, researchers have also found smoking cessation to be frequently followed by weight gain,⁴⁰ which explains our observed association between past smoking and men's MetS.

Although lifestyle, physiological and sociodemographic factors play key roles in the pathogenesis of MetS, there is also strong evidence that the syndrome is inherited.^{41–44} We evaluated the contributions of genetic factors to the phenotypic variability of MetS and its traits by heritability estimation. According to various studies from different ethnic groups, heritability of MetS ranges from approximately 19–38%.^{10–13} A Dutch study estimated a heritability of 19.2% of MetS in an isolated group of population.¹¹ A heritability of 24% in a Caribbean-Hispanic population has been reported by Lin *et al.*¹² The heritability for the Caucasian population was about 27% according to a large population-based study.¹⁰ Bayoumi *et al.*¹³ reported a heritability of 38% of MetS in healthy Omani Arab families. Besides the genetic effect itself, which could be different among the different studied populations, the discrepancy in heritability might be attributable to other factors such as different sample sizes and a different structure of pedigrees or covariates included in the analysis. Compared to different ethnic groups, relatively little information is available on the heritability of MetS in AA population. The heritability of MetS in our study was 32% after taking into account the contributions of covariates, like age, sex, alcohol consumption, smoking and physical activity level, suggesting that more than one-third of the variance in MetS was attributable to the additive effects of genes in the JHS participants. This estimate is at the higher end of the heritability range reported so far, which suggests significant genetic influences on clustering of risk factors among AA.

Reported heritability from different studies for the individual traits ranges from 10% for plasma glucose to 60% for HDL-C.^{10–14 19} Our estimates correspond well to these findings. In the present study, more than 40% of the variance in HDL-C, triglyceride and WC was attributable to genetic effects. Conversely, a moderate but significant heritability was observed for BP and FPG. In different studies as well, HDL-C, obesity and lipid profiles showed the strongest heritability, and BP and FPG had the lowest heritability.^{10–14} While genetic influence remains dominant for lipid levels and WC, it seems that for FPG and BP the environmental contribution plays a more prominent role, which was apparent by the remarkable covariate effect that was observed for FPG and BP (33% and 22%, respectively) both in our findings and in those of some other studies.^{10 12} This hypothesis is further supported by some genetic association studies, where investigators have tried to find a unifying pathogenic mechanism for the different MetS components and identify genetic variants contributing to MetS. No such work among AA was found, but a meta-analysis of 4000 Asian and Caucasian participants reviewing 25 genes reported an association between MetS and single nucleotide polymorphisms in the FTO, TCFL72, IL6, APOA5, APOC3 and CETP genes.⁴⁵ Another Swedish study found that genetic variants in the PPARG and ADRB1 genes conferred an increased risk of

future MetS.⁴⁶ All of these genes are mostly involved in lipid metabolism.^{45 46} These evidence indicate that lipid metabolism plays the central role in MetS development; and possibly, genetic impact of FPG and BP is relatively minor in MetS clusters. Our finding also indirectly supports this view as we found triglyceride, HDL-C and WC to be strongly correlated with one another and a relatively weaker correlation for BP and FPG with other traits. More importantly, we also found higher and similar heritability estimates for triglyceride, HDL-C and WC and relatively lower heritability estimates for BP and FPG, suggesting a possible similarity in the genetic mechanism of developing MetS for the AA population with other ethnic groups.

Our findings reconfirm that MetS is a complex disease and lifestyle, socioeconomic status and genetic background play important roles in the development of MetS. It was obvious from our study that the social and economic context has a disparate impact on women's cardiovascular health and that subsequent policies and health educational programmes should be particularly directed towards women for future CVD risk reduction. As the causes of MetS are reversible and the individual components are modifiable, lifestyle change such as increasing physical activity may reduce the prevalence of MetS in AA people. We found a significant and independent inverse association between MetS and adiponectin, and a positive association between MetS and homocysteine. In line with our findings, a number of recent studies also have reported similar results.^{47–51} These findings suggest that monitoring circulating adiponectin and homocysteine levels could provide useful clinical information on the risk of developing MetS and provide effective targets for intervention aimed at modifying lifestyle. However, further studies, including economic evaluations and prospective studies, should investigate whether these markers would prove useful and cost-effective in the early identification of MetS. In this study, we found considerable heritability of MetS among AA. This provides direct support for performing genome-wide association studies in this population. Our finding also supports the hypothesis of lipid metabolism playing the central role in the development of MetS and strongly encourages additional efforts to identify the underlying susceptibility genes for this syndrome in AA.

Our results should be interpreted within the context of few limitations. We acknowledge that given our cross-sectional observational design, our study can only confirm the associations of the factors with MetS but cannot prove the causality. We also recognise the considerable disagreement over the definition and diagnostic criteria related to MetS. Of the various available definitions, we used the ATPIII criteria as this is the most widely used definition in the USA.^{1 24} It can be argued, however, that some other available definition of MetS could be equally valid and produce a somewhat different result. Though we have accounted for important individual covariates, our heritability estimates were influenced

by shared environmental factors like childhood environment and neighbourhood factors, and thus our results could be slightly overestimated. One of the major strengths of our study is that our data, although cross-sectional, come from a large community-based AA population, which is vastly understudied but has high prevalence of metabolic diseases including obesity, diabetes, hypertension and others. We are not aware of any published data that reported the associated factors and quantified the heritability of MetS among AA from such a big setting. Further, assessment of sociodemographic variables in the JHS was performed uniformly and precise techniques were used to measure all physiological and biochemical values, which makes our findings reliable. JHS also has a complex and extended pedigree structure with a large sample, which provided us a more robust statistical ground to detect genetic effects than nuclear families, twin pair data or sib-pair data.

We report the associations of important factors and significant heritability estimates of MetS and its components among JHS AA families. Our data suggest the inclusion of biomarkers like adiponectin and homocysteine to improve early identification of MetS. We have demonstrated significant heritability estimates for the MetS itself, and also for its individual components. The results strongly encourage efforts to identify the underlying susceptibility genes for this syndrome in AA. Further exploration of the genetic and environmental factors of MetS among AAs will lead to a more comprehensive understanding and better therapeutic options for the syndrome, and ultimately lead to improved cardiovascular health.

Acknowledgements The authors would like to thank the Jackson Heart Study participants and the staff for their important contributions to the study of determinants of health in African Americans.

Contributors SKD and RJK conceptualised the study. RJK and RX completed the main data analysis. RJK and SKD prepared the manuscript. SYG, PR and MS contributed to the study design, interpretation of data and the preparation of the manuscript. All authors read and approved the final manuscript.

Funding This research was supported by the Intramural Research Program of the National Institutes of Health.
