

BMJ Open

BMJ Open is committed to open peer review. As part of this commitment we make the peer review history of every article we publish publicly available.

When an article is published we post the peer reviewers' comments and the authors' responses online. We also post the versions of the paper that were used during peer review. These are the versions that the peer review comments apply to.

The versions of the paper that follow are the versions that were submitted during the peer review process. They are not the versions of record or the final published versions. They should not be cited or distributed as the published version of this manuscript.

BMJ Open is an open access journal and the full, final, typeset and author-corrected version of record of the manuscript is available on our site with no access controls, subscription charges or pay-per-view fees (<http://bmjopen.bmj.com>).

If you have any questions on BMJ Open's open peer review process please email info.bmjopen@bmj.com

Abstract

Objectives

To compare the proportions of Emergency Department (ED) attendances following self-harm that result in admission between hospitals, examine whether differences are explained by severity of harm and examine the impact on spatial variation in self-harm rates of using ED attendance data versus admissions data.

Setting

A dataset of ED attendances and admissions with self-harm to four hospitals in South East London, 2009-2016 was created using linked electronic patient record data and administrative Hospital Episode Statistics.

Design

Proportions admitted following ED attendance and length of stay were compared. Variation and spatial patterning of age and sex standardised, spatially smoothed, self-harm rates by small area using attendance and admission data were compared and the association with distance travelled to hospital tested.

Results

There were 20,750 ED attendances with self-harm, 7614 (37%) resulted in admission. Proportion admitted varied substantially between hospitals with a risk ratio of 2.45 (95% CI 2.30 to 2.61) comparing most and least likely to admit. This was not altered by adjustment for patient demographics, deprivation and type of self-harm. Hospitals which admitted more had a higher proportion of admissions lasting less than 24 hours (54% of all admissions at highest admitting hospital versus 35% at lowest). A previously demonstrated pattern of lower rates of self-harm admission closer to the city centre was reduced when ED attendance rates were used to represent self-harm. This was not altered when distance travelled to hospital was adjusted for.

Conclusions

Hospitals vary substantially in likelihood of admission after ED presentation with self-harm and this is likely due to differences in hospital practices rather than in the patient population or severity of self-harm seen. Public health policy that directs resources based on self-harm admissions data risks

1
2
3 exacerbating existing health inequalities in inner-city areas where this data may underestimate rates
4 relative to other areas.

Strengths and limitations of this study

- This study links clinical records data to administrative Hospital Episode Statistics enabling the creation of a dataset of Emergency Department attendances which better represents service use for self-harm than admissions data alone and is not available from routine data.
- Use of individual level data allows investigation of the roles patient factors, type of self-harm and length of stay play in differences between hospitals.
- The focus on a specific local context has enabled us to use clinical record data and incorporate the knowledge of clinicians working within the services investigated to understand the findings but means that estimates of between hospital differences are probably conservative.
- ED attendance data shows a less biased picture of the spatial patterning of self-harm than admissions, however it may still be influenced by differences in likelihood of presentation to ED between populations.

Background

Self-harm, through both self-injury and overdose, affects over 6% of the population in England at some point in their lifetime¹ and results in an estimated 220,000 Emergency Department (ED) presentations² and over 100,000 hospital admissions³ each year in England. Increasing public health and government interest is being focussed on self-harm both as a concern in itself and as an important risk factor for future suicide⁴. Substantial geographical variations occur in the rates of self-harm^{5 6} and suicide⁷ across the country and within local authority areas. National policy in England emphasises the need for the development of suicide and self-harm prevention plans by local authorities using “localised real time data”⁸ to determine need and appropriate targeting of interventions. However, attempts to understand variations in self-harm rates in this way is hampered by the limited data routinely available.

In most countries the only nationwide, routinely available data on service use for self-harm is based on hospital admissions. Only the Republic of Ireland has established nationwide routine monitoring of presentations to EDs with self-harm that do not result in admission⁹. In England, research data on ED use following self-harm is routinely collected in hospitals in Manchester, Derby and Oxford¹⁰ but outside of these centres, the only reliably coded routine data are Hospital Episode Statistics (HES) for rates of admissions to hospital¹¹. This is an administrative dataset reported by all National Health Service (NHS) hospitals in which all hospital stays have International Classification of Diseases, version 10 (ICD-10) diagnostic codes attributed to them, including codes related to self-harm¹². Hence, much research considering how and why rates of self-harm vary between areas has relied on admission data alone. Admissions data also feature prominently in national and local public health planning. In England it is included as an indicator in the Public Health Outcomes Framework¹¹ as well as Public Health England’s area profiles¹³ whose explicit purpose is to allow monitoring and comparison of areas.

Underlying the use of admissions data for work comparing areas is the assumption that, while it contains only a minority of all self-harm that occurs, individuals from different demographic groups and geographical areas who self-harm in a similar way are equally likely to feature it in. The usual presumption is that these data represent the most severe cases of self-harm⁵, implying a uniformity of severity in the cases admitted to different hospitals. There is reason to question these assumptions. Work using data from Manchester, Oxford and Derby has compared the rates of presentation to general hospitals with self-harm using Emergency Department (ED) *attendance* data to the rates using HES *admissions* data. It found that the ratio of admission rate to attendance rate

1
2
3 varied between the three centres¹⁴. If such differences are due to variations in admission practices
4 between hospitals, they have the potential to introduce substantial biases. Using admissions data
5 could produce misleading estimates of relative rates for comparisons between areas and distort our
6 understanding of area-based health inequalities. A better understanding of biases within data on
7 admissions for self-harm could inform their use within public mental health in England and highlight
8 areas for investigation in similar datasets internationally.
9

10
11
12
13
14 This study uses data from four hospitals in South East London as a case study to investigate whether
15 there are differences between hospitals in the likelihood of admission for individuals attending EDs
16 following self-harm. London is of particular interest for work on self-harm as admissions data
17 suggest it has much lower rates of self-harm than the national average¹⁵ despite having high levels of
18 deprivation and social fragmentation, area level factors that have consistently been shown to be
19 associated with high area rates of self-harm¹⁶. Previous work has found this counter-intuitive pattern
20 replicated within London, with areas closer to the city centre having lower rates of self-harm
21 admission, a finding that remains unexplained⁶.
22
23
24
25
26
27

28 Unlike previous studies, we have linked a research dataset of ED attendances to HES admissions data
29 at the individual level. This allows the study to investigate how rates of admission vary between
30 different hospitals and to account for differences due to the socio-demographics of the population
31 served or type of self-harm seen. It also considers the impact of variations in the severity of self-
32 harm presenting to each hospital by examining average length of admission and the distance
33 individuals have to travel to get to the ED, as work in Ireland has suggested presentation after minor
34 self-injury is more common when individuals live closer to the hospital⁹. The study goes on to
35 compare the conclusions reached about the spatial patterning of self-harm when ED attendance
36 rather than admission data is used.

45 Methods

46 Aims

47
48 This study aims to compare the proportions of ED attendances for self-harm that result in
49 admissions that would be included in HES self-harm admissions data for four hospitals in South East
50 London between 2009 and 2016 and average length of stay for admitted patients, adjusting for the
51 age, sex, ethnicity and economic deprivation of those presenting and the type of self-harm. It then
52 aims to compare the amount of variation between areas and geographical patterning of self-harm
53 rates across the study area when a) ED attendances and b) admissions are used as the definition of
54
55
56
57
58
59
60

1
2
3 self-harm and to examine whether any differences persist after ED attendance rates are adjusted for
4 the distance individuals have travelled to get to the ED.
5
6

7 8 **Setting**

9
10 The study area, shown in Figure 1, consists of four London boroughs: Lambeth, Southwark,
11 Lewisham and Croydon, which stretch from central London in the north to the edge of Greater
12 London in the south and have a combined population of 1.2 million. It is served by four hospitals
13 with EDs, King's College Hospital (KCH), St Thomas' Hospital (STH), University Hospital Lewisham
14 (UHL) and Croydon University Hospital (CUH), each of which is run by a separate NHS hospital trust.
15
16 Secondary mental health care for the whole area, including liaison psychiatry services in all four EDs,
17 is provided by South London and Maudsley NHS Foundation Trust (SLaM). When examining
18 geographical patterning, rates were calculated for Lower Super Output Areas (LSOA, average
19 population 1700), of which there are 728 in the study area. These are lowest level geography
20 available in HES data and were used because there is great heterogeneity in area type across short
21 distances within London.
22
23
24
25
26
27
28

29 **Data**

30
31
32 Data was accessed via the Clinical Records Interactive Search system (CRIS), a case register created
33 from the anonymised electronic patient record of SLaM¹⁷, which is linked to HES admissions data.
34
35 CRIS contains HES data for all individuals who have ever had contact with SLaM services plus all
36 individuals living in the four boroughs of the study area, regardless of whether they have ever had
37 contact with mental health services.
38
39
40

41 **Outcome**

42 **ED attendance**

43
44
45 ED attendances by individuals aged 11 or older recorded as living within the study area at the time of
46 attendance at an ED were identified by combining CRIS and HES data. The full methods have been
47 published elsewhere¹⁸. In brief, HES Accident and Emergency data were used to identify attendances
48 to the EDs of the four study hospitals. Additional attendances were identified from CRIS records of
49 referrals to ED based liaison teams. CRIS was then used to identify any free text entries in the SLaM
50 electronic record made by a mental health liaison team or recorded as made in the ED between the
51 date and time of ED arrival and 12 hours after the date and time of ED departure. Entries containing
52 keywords relating to self-harm and suicidality (see supplementary material 1) were extracted and
53 manually coded according to whether the ED attendance was for an act of self-harm and the type of
54
55
56
57
58
59
60

1
2
3 self-harm. Throughout the study period all four EDs had 24-hour liaison teams, a policy of referring
4 all self-harm presentations to them and of recording all referrals and their reason in the electronic
5 record even if patients did not wait to be seen¹⁸.
6
7

8
9 In a small proportion of cases individuals attending EDs for self-harm may be admitted but not have
10 any psychiatric assessment within the time window specified, usually because they were too
11 physically unwell for assessment. To ensure these cases were not missed, linked HES Admitted
12 Patient Care data was checked and any admissions via ED given ICD-10 diagnostic codes X60-X84
13 (self-harm) that did not already feature in the dataset were added.
14
15
16

17
18 Part of the dataset for 2009-2013 has previously been validated against an audit dataset created in
19 EDs through a combination of forms completed by psychiatric liaison teams and searches of the ED
20 patient record¹⁸. The dataset created from electronic health records performed similarly to the audit
21 dataset, detecting 77% of all attendances and 82% of all individual patients, with no differences
22 found in the age, sex, ethnicity or marital status of those detected versus those missed.
23
24
25
26

27 HES record of admission

28
29 Admission for self-harm was extracted from the linked HES APC dataset. We used the definition of
30 admission for self-harm used by Public Health England for its 'Emergency Hospital Admissions for
31 Intentional Self-Harm' indicator¹⁹: an emergency (unplanned) admission with a 'CAUSE' ICD-10 code
32 in the range X60-X84 (Intentional self-harm). These admissions were matched to the corresponding
33 attendances where they related to the same individual at the same hospital with an admission date
34 on or one day after the date of ED attendance. This resulted in 44 admissions being matched to
35 more than one attendance, where an individual had attended two days in a row and been admitted
36 from the second attendance. In these cases, the first attendance was corrected to show it had not
37 resulted in admission.
38
39
40
41
42
43
44
45

46 Population denominator

47
48 Population denominator data were taken from Office of National Statistics mid-year estimates²⁰.
49 Due to differences in the reporting geographies between HES and ONS data, six LSOAs had to be
50 merged into 3 to make data comparable, hence 725 areas were used in analyses.
51
52
53

54 The study had access to data for all four hospitals that principally serve the study area. However, in
55 areas at the edge of the study area individuals may also attend EDs at hospitals in neighbouring
56 boroughs. HES ED data for everyone living in the study area was used to determine the proportion of
57 attendances to EDs for any reason (excluding stand-alone minor injuries and walk-in centres) that
58
59
60

were to study EDs. This proportion was used to weight the denominator population of each LSOA when calculating rates, so that rates were not misleadingly low at the edges of the study area.

Confounders

Individual age, sex, ethnicity and LSOA of residence were taken from CRIS, supplemented by HES data where CRIS was incomplete. Area-level deprivation was measured using the Index of Multiple Deprivation 2010 (IMD)²¹, a composite measure summarising multiple dimensions of deprivation at LSOA level in England. Distance to ED was measured from LSOA centroid to closest ED using ArcGIS software.

Statistical analysis

Individual-level analysis of admission following attendance

All attendances were included in analyses, with admission as the outcome. A Poisson regression model with robust error variance was used as the high prevalence of admission in the dataset made odds ratios produced from a logistic regression difficult to interpret meaningfully²². This model was two-level to account for clustering at the individual level where there were repeat attendances within the dataset. Risk ratios (RRs) for admission for each hospital were calculated and adjusted for potential confounders identified a priori: age (in five-year bands), sex, ethnicity, type of self-harm and deprivation. Wald tests were used for significance. Length of admission was grouped into < 24 hours, 1, 2, 3, 4, or 5 or more days and treated as ordinal in analyses as its distribution was very skewed. Differences between hospitals were tested with a Kruskal Wallis test. These analyses were carried out in STATA version 15.1.

LSOA-level analyses of rates of self-harm

For calculation of LSOA rates of self-harm, individuals' first admission and first attendance in the dataset were included. This was because a small number of individuals in the dataset have a large number of admissions and attendances which would have had a disproportionate influence on the rates for the small area in which they reside. Age and sex standardised rate ratios (SARs) for self-harm admission and ED attendance alone and adjusted for distance to hospital were calculated for each LSOA. SRRs were smoothed using a Besag-York-Mollie Bayesian disease mapping model²³, which includes separate spatially structured and unstructured area-level random effects, to account for over-dispersion and spatial structure. Smoothing reduces the influence of random noise given the low counts in individual areas and adjusts estimates for spatial autocorrelation.

1
2
3 For each model the amount of variation in LSOA SRRs was quantified using the 90% quantile ratio
4 (QR90). This is the ratio of the SRR for the area at the 95th centile to the SRR for the area at the 5th
5 centile and so describes the scale of variation in residual relative risk between the top and bottom
6 5% of areas. The residual SRRs after spatial smoothing and adjustment, which represent the
7 remaining variation, were mapped to display spatial patterning and plotted to allow comparison of
8 residual variation between analyses.
9

10
11
12
13
14 Analyses were carried out in R version 3.2.2. Bayesian models were run using Markov Monte Carlo
15 Chain (MCMC) simulation in OpenBUGS version 3.2.3 using the *R2OpenBUGs* routine. Results were
16 mapped in ArcMap 10.6.
17
18

19 Patient and public involvement

20
21
22 This study forms part of a wider project examining rates of self-harm in London. This project has
23 been discussed with the NIHR Maudsley BRC Service User Advisory Group who provided advice on
24 the overall aims of the project. No patients were involved in the planning or design of this study. The
25 findings have been discussed with local community groups and public health teams and will be
26 further disseminated through the BRC's PPI activity.
27
28
29
30

31 Results

32
33 During the study period During the study period 20,750 attendances to study EDs made by 12,577
34 individuals living in the study area were identified. living in the study area were identified. Of these,
35 7614 attendances (37%) by 4801 individuals resulted in an admission that was coded as self-harm in
36 HES admission data. The majority of individuals (9557, 76%) attended only once during the study
37 period while the small group of people with more than five attendances (368, 3%) accounted more
38 than a fifth of all attendances (4393, 21%).
39
40
41
42
43
44
45

46 Individual-level analysis of admission following attendance

47
48 There were 20,750 ED attendances with self-harm, 7614 (37%) of which resulted in admission. Table
49 1 shows distribution of age, sex, ethnicity, types of self-harm and deprivation for ED attendances and
50 admissions. Table 2 shows the proportions of ED attendances that resulted in admissions by hospital
51 and the distribution of lengths of stay. There were substantial differences in the proportions being
52 admitted between the four hospitals in the study area: compared to KCH, which admitted the lowest
53 proportion, the RRs for the other three hospitals were all 2 or above, with the greatest difference for
54 CUH (RR 2.45 (95% confidence interval (CI), 2.30 to 2.61), $p < 0.0001$). The effect sizes were almost
55
56
57
58
59
60

1
2
3 unchanged when adjusted for the sex, age and ethnicity of the individuals attending, the type of self-
4 harm they presented with and the level of deprivation in the local areas in which they lived, for
5 example the RR for CUH versus KCH reduced to 2.41 (2.27 to 2.55, $p < 0.0001$). The distribution of
6 lengths of admissions also varied significantly between hospitals (Kruskal Wallis test for equality,
7 $p = 0.0001$). Notably more than half (53.6%) of the admissions to CUH were for less than 24 hours,
8 compared to 34.5% at KCH. Conversely, 28.3% of KCH admissions lasted 2-4 or 5+ days compared to
9 15.5% of CUH admissions. The other two hospitals, STH and UHL lie between these two extremes.

16 LSOA-level analyses of rates of self-harm

17
18 Modelling smoothed, age and sex standardised rates of self-harm for LSOAs based on attendance
19 and admission data separately demonstrated that rates based on admissions data had greater
20 spatial variation. The QR90 for SRRs based on attendance was 2.87 (95% Credible interval (CrI), 2.65
21 to 3.13) while that for admissions was 4.51 (3.99 to 5.12). Plots of the residual SRRs, included in
22 supplementary figure 1, demonstrate that LSOAs with both high and low rates estimated using
23 admissions data tend to have less extreme rates when attendance data is used.

24
25 Figure 2 visualises the effect of these differences in the attendance and admissions datasets when
26 the geographical patterning of self-harm is considered. LSOA rates of self-harm *admission* are
27 clustered with, in general, lower rates of self-harm in areas closer to the city centre. As is shown in
28 supplementary figure 2 and previous work⁶ these patterns are not explained by area deprivation but
29 in fact strengthen when deprivation is adjusted for. When ED *attendance* data is used there is less
30 difference between rates of self-harm in inner and outer-city areas. Some inner-city areas with
31 apparently below average rates of self-harm using admission data are shown to have above average
32 rates of ED attendance for self-harm, although an overall pattern of lower rates in the inner-city
33 remains, all be it with smaller differences in standardised rates. This is shown when the SRRs for the
34 quintile of LSOAs closest to the city centre versus the furthest in the two datasets are compared. For
35 admissions the SRR is 0.65 (0.40-1.02)¹ whilst for attendances it is 0.84 (0.60-1.13) suggesting
36 admissions data overestimate the effect of proximity to the city centre in lowering rates. Adjusting
37 for the distance individuals had to travel to reach their closet ED makes little difference to the spatial
38 patterning seen when ED attendance data is used. This is reflected in the SRR for self-harm ED
39 attendance for each 1km increase in LSOA distance from hospital of 0.96 (CrI 0.91-1.01).

56
57
58
59
60

¹ While the credible interval for this estimate crosses 1, the effect size is very similar to that found in previous work on the same geographical area which used data from more years and hospitals (0.67 (0.48-0.89))⁶, suggesting that the wide CrI is due to imprecision from a smaller sample size rather than indicating an absence of effect. In this analysis a smaller dataset was used so that it matched the ED attendance data available.

Discussion

Principal findings

In this South East London case study area the HES admission data widely used to represent self-harm rates contains only around a third of all hospital treated self-harm. Importantly, the likelihood that someone attending an ED with self-harm will be admitted and feature in the HES admission dataset varies substantially according to which ED they attend, with one study hospital almost two and a half times more likely to admit than another. This echoes previous findings of differences in the ratio of attendance rates to admission rates between other English cities¹⁴ and extends them by demonstrating that it is not explained by differences in the demographics of those attending, the deprivation of the areas the EDs served or the type of self-harm people were presenting with. This strengthens the case that differences reflect a difference in practices between the hospitals.

Comparison of the lengths of stay between hospitals suggests the difference also is not explained by differences in the severity of the self-harm presenting. The hospital with the lowest proportion admitted had the longest average length of stay and the lowest proportion of very short (under 24 hour) admissions, whilst the hospital with the highest proportion admitted had more than half of its admissions lasting less than 24 hours. This points to differences between hospitals in how likely they are to admit less severe cases.

There were substantial differences in the spatial patterning of self-harm rates seen when different data sources were used. The pattern of clustering of low rates of self-harm in inner city areas and higher rates of self-harm in areas further from the city centre seen when admission data is used becomes less marked when ED attendance data is used instead. In particular, there are many inner-city areas that appear to have low standardised rates of self-harm using admissions data that are shown to have average or even high rates using ED attendance data. The absence of an association between LSOA self-harm ED attendance rates and distance travelled to hospital, as well as the length of stay findings described above, suggest these differences are not due to the shorter travel times to EDs for individuals in inner city areas encouraging use of ED services for more minor self-harm that might not use hospital services at all in other areas.

Overall, this study demonstrates that hospitals vary substantially in the likelihood that someone attending ED with self-harm will be admitted, and this is probably not dictated by the severity of self-harm. Discussions with staff within the psychiatric liaison services from the four hospitals studied during the study period (S Cross 2019, personal communication, 2nd April; G Ranjith 2019,

1
2
3 personal communication, 3rd March) have highlighted largely policy-based potential explanations for
4 the difference in admissions seen. For example, hospitals vary in the established ways of managing
5 patients awaiting psychiatric assessment in the ED who were likely to breach national ED waiting
6 time targets²⁴ and the accepted locations for patients to receive brief courses of treatment. There
7
8 may also be more general differences: for example, hospitals facing greater general demand on beds
9
10
11 may have greater severity thresholds for admission.

13 14 Strengths and Limitations

15
16 The lack of reliable routine data on ED attendances for self-harm means that this study could only be
17 done in a context where ED attendance could be ascertained in a different way. The availability of
18 clinical records linked to HES data at the individual level within CRIS has allowed us to investigate the
19 potential role patient factors, type of self-harm and length of stay play in differences between
20 hospitals. A focus on a specific local context has also enabled us to use the knowledge of clinicians
21 working within the services investigated to understand the findings.
22
23
24
25
26

27 At a national scale, there are likely to be greater differences in practices between different hospitals
28 than those seen within one area, so this case study is probably a conservative estimate of the effects
29 of such biases. The specific findings relate to a particular geographical area, South East London,
30 however, the limitations it highlights in the use of admissions data to monitor and understand self-
31 harm are relevant across the national area covered by HES data and in other international contexts
32 where routine admissions data is used.
33
34
35
36

37
38 The use of mental health clinical records to ascertain ED attendances for self-harm will miss some
39 cases. Previous validation work with part of this dataset suggests it detected a similar proportion of
40 ED attendances to an audit dataset based on staff in the ED filling out forms and manual checking of
41 ED notes for cases of self-harm and there were no differences in those detected or missed based on
42 patient demographics¹⁸. Nonetheless, the implication is that the true number of attendances is
43 higher, so the proportions admitted are likely to be an overestimate. It is possible that despite
44 liaison services in the four EDs being provided by the same mental health trust with apparently
45 uniform referral policies, a greater proportion of all presentations are detected for some EDs than
46 others in this dataset. This would make admission rates for EDs with a high proportion of
47 attendances detected look lower. There is no way to test this with the data available, however the
48 increase in the proportion of very short admissions seen in hospitals with higher admission rates
49 supports the conclusion that these findings illuminate real differences in hospital admission
50 practices.
51
52
53
54
55
56
57
58
59
60

1
2
3 While this study shows how admissions data differs to attendance data, it needs to be borne in mind
4 that the majority of self-harm in the community, particularly self-injury, does not present to hospital
5 services at all²⁵. Hospital presenting self-harm is of interest as it is associated with high levels of
6 psychiatric morbidity²⁶ as well as the physical harm caused and has been shown to be an important
7 risk factor for future suicide⁴. However, the processes that determine whether someone who has
8 self-harmed in the community presents to the ED may well vary between population groups and
9 geographical areas, meaning that even ED attendance data may not fully represent true variations in
10 rates of self-harm in the community between areas.
11
12
13
14
15
16

17 Implications

18
19
20 Differences in likelihood of admission between hospitals will bias estimates of rates of self-harm for
21 different areas. This has the potential to exacerbate health inequalities if it results in resources being
22 directed away from disadvantaged areas and populations on the basis of an underestimate of rates.
23 Previous research has found lower rates of admission for self-harm in English city centres compared
24 to the suburbs^{6 16}. This study suggests such findings may be partly explained by admission practices
25 resulting in an underestimate of self-harm in the inner cities when admission data is used.
26
27
28
29

30 Underestimation of self-harm rates in this study mainly effected the boroughs of Lambeth and
31 Southwark. These boroughs include areas with high levels of deprivation and substantial black and
32 minority ethnic populations and experience higher rates of adverse health outcomes²⁷ including
33 higher rates of lifetime suicidal behaviours than the national average on community surveys²⁸.
34
35
36

37 Current reliance of public health services in these boroughs on self-harm admissions data to
38 formulate their suicide and self-harm prevention strategies²⁹ risks failing to identify need in already
39 disadvantaged populations.
40
41

42 If the hospital practices driving lower admissions are more typical of hospitals serving more deprived
43 inner-city areas or otherwise under greater resource pressure, it is likely that these patterns are
44 being replicated elsewhere in the country. At a national level, London has much lower rates of self-
45 harm admissions than the English average¹⁵ however these findings provide reason to be cautious in
46 interpreting this as meaning there is truly lower underlying risk in the capital. Likewise, in other
47 settings, research findings and public health planning based on admissions data need to be alert to
48 the potential influence of such biases.
49
50
51
52
53

54
55 Routinely collected data on attendances to medical services following self-harm will always have an
56 important role in research and public health planning both in England and internationally. It provides
57 more comprehensive coverage and regular updates than research datasets can, allowing variations
58 between areas and over time to be examined. This study suggests that routine data covering ED
59
60

1
2
3 attendances would be more appropriately used for these purposes. Such a dataset was included as a
4 “placeholder indicator” in Public Health England’s Public Health Outcomes Framework (PHOF) from
5 2015¹¹ as a statement of intent to begin using such data as soon as it became available.
6
7

8 Unfortunately, the lack of a reliable source for the measure means it has never been produced and is
9 now earmarked for removal in the next iteration of the PHOF³⁰. The findings of this paper suggest
10 that efforts to find a way to create a reliable ED self-harm dataset should remain a priority. The
11 widespread use of electronic health records by mental health trusts and their increasing
12 incorporation into linked research databases through systems including CRIS may provide avenues to
13 do this in future.
14
15
16
17

18 19 20 Conclusions

21
22
23 Currently in England, as in many other countries, hospital admissions are the only comprehensive,
24 reliably coded data on the incidence of non-fatal self-harm available and so are widely used in
25 research and as a public health indicator. This analysis demonstrates that doing so risks
26 underestimating relative rates in inner city areas and so exacerbating existing health inequalities.
27
28 Hospitals differ substantially in the proportions of individuals attending EDs with self-harm who get
29 admitted. These differences are not explained by patient characteristics, type of self-harm or
30 indicators of the severity of self-harm which suggests differences in hospital policies and practices
31 are key. ED attendances for self-harm would provide a less biased estimate of area rates for
32 comparisons hence making such data routinely available should be a public health priority.

Declarations

Ethics approval and consent to participate

Research using data within CRIS is covered by a database approval from Oxford REC C (18/SC/0372), this project was approved by the CRIS Oversight Committee (Project number 14-026). Linkage of HES data to CRIS was given approval by the NHS Health Research Authority Confidentiality Advisory Group under Section 251 of the NHS Act 2006 in 2011 (reference ECC 3-04(f)/2011).

Consent for publication

Not applicable

Availability of data and material

The datasets generated and/or analysed during the current study are not publicly available. Data are owned by a third party, the Biomedical Research Centre (BRC) Clinical Records Interactive Search (CRIS) tool, which provides access to anonymised data derived from SLaM electronic medical records. These data can only be accessed by permitted individuals with honorary contracts with SLaM from within a secure firewall (i.e., remote access is not possible and the data cannot be sent elsewhere), in the same manner as the authors.

Competing interests

The authors declare that they have no competing interests.

Funding

CP is funded by a Wellcome Trust Research Training Fellowship (grant number 105757/Z/14/Z). This paper represents independent research part funded by the National Institute for Health Research

STROBE Statement—Checklist of items that should be included in reports of *cross-sectional studies*

	Item No	Recommendation	Page No
Title and abstract	1	(a) Indicate the study's design with a commonly used term in the title or the abstract	1
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	2
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	3-4
Objectives	3	State specific objectives, including any prespecified hypotheses	4
Methods			
Study design	4	Present key elements of study design early in the paper	5-7
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	5
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants	5
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	5-7
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	5-7
Bias	9	Describe any efforts to address potential sources of bias	7
Study size	10	Explain how the study size was arrived at	N/a
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	7
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	7-8
		(b) Describe any methods used to examine subgroups and interactions	N/a
		(c) Explain how missing data were addressed	N/a
		(d) If applicable, describe analytical methods taking account of sampling strategy	N/a
		(e) Describe any sensitivity analyses	N/a
Results			
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed	8
		(b) Give reasons for non-participation at each stage	N/a
		(c) Consider use of a flow diagram	N/a
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders	15 (T1)
		(b) Indicate number of participants with missing data for each variable of interest	15 (T1)
Outcome data	15*	Report numbers of outcome events or summary measures	8, 15 (T1)

1 2 3 4 5 6 7 8 9 10	Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included	16 (T2)
11 12 13			(b) Report category boundaries when continuous variables were categorized	N/a
14 15 16 17 18 19			(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period	N/a
20 21 22 23	Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses	N/a
24	Discussion			
25 26 27 28 29 30	Key results	18	Summarise key results with reference to study objectives	9
31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60	Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss both direction and magnitude of any potential bias	10-11
	Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence	11-12
	Generalisability	21	Discuss the generalisability (external validity) of the study results	10-12
	Other information			
	Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based	21

*Give information separately for exposed and unexposed groups.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). Abstract

Objectives

To compare the proportions of Emergency Department (ED) attendances following self-harm that result in admission between hospitals, examine whether differences are explained by severity of harm and examine the impact on spatial variation in self-harm rates of using ED attendance data versus admissions data.

Setting

A dataset of ED attendances and admissions with self-harm to four hospitals in South East London, 2009-2016 was created using linked electronic patient record data and administrative Hospital Episode Statistics.

Design

Proportions admitted following ED attendance and length of stay were compared. Variation and spatial patterning of age and sex standardised, spatially smoothed, self-harm rates by small area using attendance and admission data were compared and the association with distance travelled to hospital tested.

Results

There were 20,750 ED attendances with self-harm, 7614 (37%) resulted in admission. Proportion admitted varied substantially between hospitals with a risk ratio of 2.45 (95% CI 2.30 to 2.61) comparing most and least likely to admit. This was not altered by adjustment for patient demographics, deprivation and type of self-harm. Hospitals which admitted more had a higher proportion of admissions lasting less than 24 hours (54% of all admissions at highest admitting hospital versus 35% at lowest). A previously demonstrated pattern of lower rates of self-harm admission closer to the city centre was reduced when ED attendance rates were used to represent self-harm. This was not altered when distance travelled to hospital was adjusted for.

Conclusions

Hospitals vary substantially in likelihood of admission after ED presentation with self-harm and this is likely due to differences in hospital practices rather than in the patient population or severity of self-harm seen. Public health policy that directs resources based on self-harm admissions data could

Strengths and limitations of this study

- This study links clinical records data to administrative Hospital Episode Statistics enabling the creation of a dataset of Emergency Department attendances which better represents service use for self-harm than admissions data alone and is not available from routine data.
- Use of individual level data allows investigation of the roles patient factors, type of self-harm and length of stay play in differences between hospitals.
- The focus on a specific local context has enabled us to use clinical record data and incorporate the knowledge of clinicians working within the services investigated to understand the findings but means that estimates of between hospital differences are probably conservative.
- ED attendance data shows a less biased picture of the spatial patterning of self-harm than admissions, however it may still be influenced by differences in likelihood of presentation to ED between populations.

Background

Self-harm, through both self-injury and overdose, affects over 6% of the population in England at some point in their lifetime¹ and results in an estimated 220,000 Emergency Department (ED) presentations² and over 100,000 hospital admissions³ each year in England. Increasing public health and government interest is being focussed on self-harm both as a concern in itself and as an important risk factor for future suicide⁴. Substantial geographical variations occur in the rates of self-harm^{5 6} and suicide⁷ across the country and within local authority areas. National policy in England emphasises the need for the development of suicide and self-harm prevention plans by local authorities using “localised real time data”⁸ to determine need and appropriate targeting of interventions. However, attempts to understand variations in self-harm rates in this way is hampered by the limited data routinely available.

In most countries the only nationwide, routinely available data on service use for self-harm is based on hospital admissions. Only the Republic of Ireland has established nationwide routine monitoring of presentations to EDs with self-harm that do not result in admission⁹. In England, research data on ED use following self-harm is routinely collected in hospitals in Manchester, Derby and Oxford¹⁰ but outside of these centres, the only reliably coded routine data are Hospital Episode Statistics (HES) for rates of admissions to hospital¹¹. This is an administrative dataset reported by all National Health Service (NHS) hospitals in which all hospital stays have International Classification of Diseases, version 10 (ICD-10) diagnostic codes attributed to them, including codes related to self-harm¹². Hence, much research considering how and why rates of self-harm vary between areas has relied on admission data alone. Admissions data also feature prominently in national and local public health planning. In England it is included as an indicator in the Public Health Outcomes Framework¹¹ as well as Public Health England’s area profiles¹³ whose explicit purpose is to allow monitoring and comparison of areas.

Underlying the use of admissions data for work comparing areas is the assumption that, while it contains only a minority of all self-harm that occurs, individuals from different demographic groups and geographical areas who self-harm in a similar way are equally likely to feature it in. The usual presumption is that these data represent the most severe cases of self-harm⁵, implying a uniformity of severity in the cases admitted to different hospitals. There is reason to question these assumptions. Work using data from Manchester, Oxford and Derby has compared the rates of presentation to general hospitals with self-harm using Emergency Department (ED) *attendance* data to the rates using HES *admissions* data. It found that the ratio of admission rate to attendance rate

1
2
3 varied between the three centres¹⁴. If such differences are due to variations in admission practices
4 between hospitals, they have the potential to introduce substantial biases. Using admissions data
5 could produce misleading estimates of relative rates for comparisons between areas and distort our
6 understanding of area-based health inequalities. A better understanding of biases within data on
7 admissions for self-harm could inform their use within public mental health in England and highlight
8 areas for investigation in similar datasets internationally.
9

10
11
12
13
14 This study uses data from four hospitals in South East London as a case study to investigate whether
15 there are differences between hospitals in the likelihood of admission for individuals attending EDs
16 following self-harm. London is of particular interest for work on self-harm as admissions data
17 suggest it has much lower rates of self-harm than the national average¹⁵ despite having high levels of
18 deprivation and social fragmentation, area level factors that have consistently been shown to be
19 associated with high area rates of self-harm¹⁶. Previous work has found this counter-intuitive pattern
20 replicated within London, with areas closer to the city centre having lower rates of self-harm
21 admission, a finding that remains unexplained⁶.
22
23
24
25
26
27

28 Unlike previous studies, we have linked a research dataset of ED attendances to HES admissions data
29 at the individual level. This allows the study to investigate how rates of admission vary between
30 different hospitals and to account for differences due to the socio-demographics of the population
31 served or type of self-harm seen. It also considers the impact of variations in the severity of self-
32 harm presenting to each hospital by examining average length of admission and the distance
33 individuals have to travel to get to the ED, as work in Ireland has suggested presentation after minor
34 self-injury is more common when individuals live closer to the hospital⁹. The study goes on to
35 compare the conclusions reached about the spatial patterning of self-harm when ED attendance
36 rather than admission data were used.

45 Methods

46 Aims

47
48 This study aims to compare the proportions of ED attendances for self-harm that result in
49 admissions that would be included in HES self-harm admissions data for four hospitals in South East
50 London between 2009 and 2016 and average length of stay for admitted patients, adjusting for the
51 age, sex, ethnicity and economic deprivation of those presenting and the type of self-harm. It then
52 aims to compare the amount of variation between areas and geographical patterning of self-harm
53 rates across the study area when a) ED attendances and b) admissions are used as the definition of
54
55
56
57
58
59
60

1
2
3 self-harm and to examine whether any differences persist after ED attendance rates are adjusted for
4 the distance individuals have travelled to get to the ED.
5
6

7 8 Setting

9
10 The study area, shown in Figure 1, consists of four London boroughs: Lambeth, Southwark,
11 Lewisham and Croydon, which stretch from central London in the north to the edge of Greater
12 London in the south and have a combined population of 1.2 million. It is served by four hospitals
13 with EDs, King's College Hospital (KCH), St Thomas' Hospital (STH), University Hospital Lewisham
14 (UHL) and Croydon University Hospital (CUH), each of which is run by a separate NHS hospital trust.
15
16 Secondary mental health care for the whole area, including liaison psychiatry services in all four EDs,
17 is provided by South London and Maudsley NHS Foundation Trust (SLaM). When examining
18 geographical patterning, rates were calculated for Lower Super Output Areas (LSOA, average
19 population 1700), of which there are 728 in the study area. These are lowest level geography
20 available in HES data and were used because there is great heterogeneity in area type across short
21 distances within London.
22
23
24
25
26
27
28

29 Data

30
31
32 Data was accessed via the Clinical Records Interactive Search system (CRIS), a case register created
33 from the anonymised electronic patient record of SLaM¹⁷, which is linked to HES admissions data.
34
35 CRIS contains HES data for all individuals who have ever had contact with SLaM services plus all
36 individuals living in the four boroughs of the study area, regardless of whether they have ever had
37 contact with mental health services.
38
39
40

41 Outcome

42 ED attendance

43
44
45 ED attendances by individuals aged 11 or older recorded as living within the study area at the time of
46 attendance at an ED were identified by combining CRIS and HES data. The full methods have been
47 published elsewhere¹⁸. In brief, HES Accident and Emergency data were used to identify attendances
48 to the EDs of the four study hospitals. Additional attendances were identified from CRIS records of
49 referrals to ED based liaison teams. CRIS was then used to identify any free text entries in the SLaM
50 electronic record made by a mental health liaison team or recorded as made in the ED between the
51 date and time of ED arrival and 12 hours after the date and time of ED departure. Entries containing
52 keywords relating to self-harm and suicidality (see supplementary material 1) were extracted and
53 manually coded according to whether the ED attendance was for an act of self-harm and the type of
54
55
56
57
58
59
60

1
2
3 self-harm. Throughout the study period all four EDs had 24-hour liaison teams, a policy of referring
4 all self-harm presentations to them and of recording all referrals and their reason in the electronic
5 record even if patients did not wait to be seen¹⁸.
6
7

8
9 In a small proportion of cases individuals attending EDs for self-harm may be admitted but not have
10 any psychiatric assessment within the time window specified, usually because they were too
11 physically unwell for assessment. To ensure these cases were not missed, linked HES Admitted
12 Patient Care data was checked and any admissions via ED given ICD-10 diagnostic codes X60-X84
13 (self-harm) that did not already feature in the dataset were added.
14
15
16

17
18 Part of the dataset for 2009-2013 has previously been validated against an audit dataset created in
19 EDs through a combination of forms completed by psychiatric liaison teams and searches of the ED
20 patient record¹⁸. The dataset created from electronic health records performed similarly to the audit
21 dataset, detecting 77% of all attendances and 82% of all individual patients, with no differences
22 found in the age, sex, ethnicity or marital status of those detected versus those missed.
23
24
25
26

27 HES record of admission

28
29 Admission for self-harm was extracted from the linked HES APC dataset. We used the definition of
30 admission for self-harm used by Public Health England for its 'Emergency Hospital Admissions for
31 Intentional Self-Harm' indicator¹⁹: an emergency (unplanned) admission with a 'CAUSE' ICD-10 code
32 in the range X60-X84 (Intentional self-harm). These admissions were matched to the corresponding
33 attendances where they related to the same individual at the same hospital with an admission date
34 on or one day after the date of ED attendance. This resulted in 44 admissions being matched to
35 more than one attendance, where an individual had attended two days in a row and been admitted
36 from the second attendance. In these cases, the first attendance was corrected to show it had not
37 resulted in admission.

41
42
43
44
45

46 Population denominator

47
48 Population denominator data were taken from Office of National Statistics mid-year estimates²⁰.
49 Due to differences in the reporting geographies between HES and ONS data, six LSOAs had to be
50 merged into 3 to make data comparable, hence 725 areas were used in analyses.
51
52
53

54 The study had access to data for all four hospitals that principally serve the study area. However, in
55 areas at the edge of the study area individuals may also attend EDs at hospitals in neighbouring
56 boroughs. HES ED data for everyone living in the study area was used to determine the proportion of
57 attendances to EDs for any reason (excluding stand-alone minor injuries and walk-in centres) that
58
59
60

were to study EDs. This proportion was used to weight the denominator population of each LSOA when calculating rates, so that rates were not misleadingly low at the edges of the study area.

Confounders

Individual age, sex, ethnicity and LSOA of residence were taken from CRIS, supplemented by HES data where CRIS was incomplete. Area-level deprivation was measured using the Index of Multiple Deprivation 2010 (IMD)²¹, a composite measure summarising multiple dimensions of deprivation at LSOA level in England. Distance to ED was measured from LSOA centroid to closest ED using ArcGIS software.

Statistical analysis

Individual-level analysis of admission following attendance

All attendances were included in analyses, with admission as the outcome. A Poisson regression model with robust error variance was used as the high prevalence of admission in the dataset made odds ratios produced from a logistic regression difficult to interpret meaningfully²². This model was two-level to account for clustering at the individual level where there were repeat attendances within the dataset. Risk ratios (RRs) for admission for each hospital were calculated and adjusted for potential confounders identified a priori: age (in five-year bands), sex, ethnicity, type of self-harm and deprivation. Wald tests were used for significance. Length of admission was grouped into < 24 hours, 1, 2, 3, 4, or 5 or more days and treated as ordinal in analyses as its distribution was very skewed. Differences between hospitals were tested with a Kruskal Wallis test. These analyses were carried out in STATA version 15.1.

LSOA-level analyses of rates of self-harm

For calculation of LSOA rates of self-harm, individuals' first admission and first attendance in the dataset were included. This was because a small number of individuals in the dataset have a large number of admissions and attendances which would have had a disproportionate influence on the rates for the small area in which they reside. Age and sex standardised rate ratios (SRRs) for self-harm admission and ED attendance alone and adjusted for distance to hospital were calculated for each LSOA. SRRs were smoothed using a Besag-York-Mollie Bayesian disease mapping model²³, which includes separate spatially structured and unstructured area-level random effects, to account for over-dispersion and spatial structure. Smoothing reduces the influence of random noise given the low counts in individual areas and adjusts estimates for spatial autocorrelation.

1
2
3 For each model the amount of variation in LSOA SRRs was quantified using the 90% quantile ratio
4 (QR90). This is the ratio of the SRR for the area at the 95th centile to the SRR for the area at the 5th
5 centile and so describes the scale of variation in residual relative risk between the top and bottom
6 5% of areas. The residual SRRs after spatial smoothing and adjustment, which represent the
7 remaining variation, were mapped to display spatial patterning and plotted to allow comparison of
8 residual variation between analyses.
9

10
11
12
13
14 Analyses were carried out in R version 3.2.2. Bayesian models were run using Markov Monte Carlo
15 Chain (MCMC) simulation in OpenBUGS version 3.2.3 using the *R2OpenBUGs* routine. Results were
16 mapped in ArcMap 10.6.
17
18

19 Patient and public involvement

20
21
22 This study forms part of a wider project examining rates of self-harm in London. This project has
23 been discussed with the NIHR Maudsley BRC Service User Advisory Group who provided advice on
24 the overall aims of the project. No patients were involved in the planning or design of this study. The
25 findings have been discussed with local community groups and public health teams and will be
26 further disseminated through the BRC's PPI activity.
27
28
29
30

31 Results

32
33 During the study period 20,750 attendances to study EDs made by 12,577 individuals living in the
34 study area were identified. Of these, 7614 attendances (37%) by 4801 individuals resulted in an
35 admission that was coded as self-harm in HES admission data. The majority of individuals (9557,
36 76%) attended only once during the study period while the small group of people with more than
37 five attendances (368, 3%) accounted more than a fifth of all attendances (4393, 21%).

43
44

45 Individual-level analysis of admission following attendance

46
47 There were 20,750 ED attendances with self-harm, 7614 (37%) of which resulted in admission. Table
48 1 shows distribution of age, sex, ethnicity, types of self-harm and deprivation for ED attendances and
49 admissions. Table 2 shows the proportions of ED attendances that resulted in admissions by hospital
50 and the distribution of lengths of stay. There were substantial differences in the proportions being
51 admitted between the four hospitals in the study area: compared to KCH, which admitted the lowest
52 proportion, the RRs for the other three hospitals were all 2 or above, with the greatest difference for
53 CUH (RR 2.45 (95% confidence interval (CI), 2.30 to 2.61), $p < 0.0001$). The effect sizes were almost
54 unchanged when adjusted for the sex, age and ethnicity of the individuals attending, the type of self-
55
56
57
58
59
60

1
2
3 harm they presented with and the level of deprivation in the local areas in which they lived, for
4 example the RR for CUH versus KCH reduced to 2.41 (2.27 to 2.55, $p < 0.0001$). The distribution of
5 lengths of admissions also varied significantly between hospitals (Kruskal Wallis test for equality,
6 $p = 0.0001$). Notably more than half (53.6%) of the admissions to CUH were for less than 24 hours,
7 compared to 34.5% at KCH. Conversely, 28.3% of KCH admissions lasted 2-4 or 5+ days compared to
8 15.5% of CUH admissions. The other two hospitals, STH and UHL lie between these two extremes.
9

14 LSOA-level analyses of rates of self-harm

16 Modelling smoothed, age and sex standardised rates of self-harm for LSOAs based on attendance
17 and admission data separately demonstrated that rates based on admissions data had greater
18 spatial variation. The QR90 for SRRs based on attendance was 2.87 (95% Credible interval (CrI), 2.65
19 to 3.13) while that for admissions was 4.51 (3.99 to 5.12). Plots of the residual SRRs, included in
20 supplementary figure 1, demonstrate that LSOAs with both high and low rates estimated using
21 admissions data tend to have less extreme rates when attendance data is used.
22
23
24
25
26

27 Figure 2 visualises the effect of these differences in the attendance and admissions datasets when
28 the geographical patterning of self-harm is considered. LSOA rates of self-harm *admission* are
29 clustered with, in general, lower rates of self-harm in areas closer to the city centre. As is shown in
30 supplementary figure 2 and previous work⁶ these patterns are not explained by area deprivation but
31 in fact strengthen when deprivation is adjusted for. When ED *attendance* data is used there is less
32 difference between rates of self-harm in inner and outer-city areas. Some inner-city areas with
33 apparently below average rates of self-harm using admission data are shown to have above average
34 rates of ED attendance for self-harm, although an overall pattern of lower rates in the inner-city
35 remains, all be it with smaller differences in standardised rates. This is shown when the SRRs for the
36 quintile of LSOAs closest to the city centre versus the furthest in the two datasets are compared. For
37 admissions the SRR is 0.65 (0.40-1.02)¹ whilst for attendances it is 0.84 (0.60-1.13) suggesting
38 admissions data overestimate the effect of proximity to the city centre in lowering rates. Adjusting
39 for the distance individuals had to travel to reach their closet ED makes little difference to the spatial
40 patterning seen when ED attendance data is used. This is reflected in the SRR for self-harm ED
41 attendance for each 1km increase in LSOA distance from hospital of 0.96 (CrI 0.91-1.01).
42
43
44
45
46
47
48
49
50
51
52
53
54
55

57 ¹ While the credible interval for this estimate crosses 1, the effect size is very similar to that found in previous
58 work on the same geographical area which used data from more years and hospitals (0.67 (0.48-0.89))⁶,
59 suggesting that the wide CrI is due to imprecision from a smaller sample size rather than indicating an absence
60 of effect. In this analysis a smaller dataset was used so that it matched the ED attendance data available.

Discussion

Principal findings

In this South East London case study area the HES admission data widely used to represent self-harm rates contains only around a third of all hospital treated self-harm. Importantly, the likelihood that someone attending an ED with self-harm will be admitted and feature in the HES admission dataset varies substantially according to which ED they attend, with one study hospital almost two and a half times more likely to admit than another. This echoes previous findings of differences in the ratio of attendance rates to admission rates between other English cities¹⁴ and extends them by demonstrating that it is not explained by differences in the demographics of those attending, the deprivation of the areas the EDs served or the type of self-harm people were presenting with. This strengthens the case that differences reflect a difference in practices between the hospitals.

Comparison of the lengths of stay between hospitals suggests the difference also is not explained by differences in the severity of the self-harm presenting. The hospital with the lowest proportion admitted had the longest average length of stay and the lowest proportion of very short (under 24 hour) admissions, whilst the hospital with the highest proportion admitted had more than half of its admissions lasting less than 24 hours. This points to differences between hospitals in how likely they are to admit less severe cases.

There were substantial differences in the spatial patterning of self-harm rates seen when different data sources were used. The pattern of clustering of low rates of self-harm in inner city areas and higher rates of self-harm in areas further from the city centre seen when admission data is used becomes less marked when ED attendance data is used instead. In particular, there are many inner-city areas that appear to have low standardised rates of self-harm using admissions data that are shown to have average or even high rates using ED attendance data. The absence of an association between LSOA self-harm ED attendance rates and distance travelled to hospital, as well as the length of stay findings described above, suggest these differences are not due to the shorter travel times to EDs for individuals in inner city areas encouraging use of ED services for more minor self-harm that might not use hospital services at all in other areas.

Overall, this study demonstrates that hospitals vary substantially in the likelihood that someone attending ED with self-harm will be admitted, and this is probably not dictated by the severity of self-harm. Discussions with staff within the psychiatric liaison services from the four hospitals studied during the study period (S Cross 2019, personal communication, 2nd April; G Ranjith 2019,

1
2
3 personal communication, 3rd March) have highlighted largely policy-based potential explanations for
4 the difference in admissions seen. For example, hospitals vary in the established ways of managing
5 patients awaiting psychiatric assessment in the ED who were likely to breach national ED waiting
6 time targets²⁴ and the accepted locations for patients to receive brief courses of treatment. There
7
8 may also be more general differences: for example, hospitals facing greater general demand on beds
9
10
11
12 may have greater severity thresholds for admission.

13 14 Strengths and Limitations

15
16 The lack of reliable routine data on ED attendances for self-harm means that this study could only be
17 done in a context where ED attendance could be ascertained in a different way. The availability of
18 clinical records linked to HES data at the individual level within CRIS has allowed us to investigate the
19 potential role patient factors, type of self-harm and length of stay play in differences between
20 hospitals. A focus on a specific local context has also enabled us to use the knowledge of clinicians
21 working within the services investigated to understand the findings.

22
23 At a national scale, there are likely to be greater differences in practices between different hospitals
24 than those seen within one area, so this case study is probably a conservative estimate of the effects
25 of such biases. The specific findings relate to a particular geographical area, South East London,
26 however, the limitations it highlights in the use of admissions data to monitor and understand self-
27 harm are relevant across the national area covered by HES data and in other international contexts
28 where routine admissions data is used.

29
30 The use of mental health clinical records to ascertain ED attendances for self-harm will miss some
31 cases. Previous validation work with part of this dataset suggests it detected a similar proportion of
32 ED attendances to an audit dataset based on staff in the ED filling out forms and manual checking of
33 ED notes for cases of self-harm and there were no differences in those detected or missed based on
34 patient demographics¹⁸. Nonetheless, the implication is that the true number of attendances is
35 higher, so the proportions admitted are likely to be an overestimate. It is possible that despite
36 liaison services in the four EDs being provided by the same mental health trust with apparently
37 uniform referral policies, a greater proportion of all presentations are detected for some EDs than
38 others in this dataset. This would make admission rates for EDs with a high proportion of
39 attendances detected look lower. There is no way to test this with the data available, however the
40 increase in the proportion of very short admissions seen in hospitals with higher admission rates
41 supports the conclusion that these findings illuminate real differences in hospital admission
42 practices.

1
2
3 While this study shows how admissions data differs to attendance data, it needs to be borne in mind
4 that the majority of self-harm in the community, particularly self-injury, does not present to hospital
5 services at all²⁵. Hospital presenting self-harm is of interest as it is associated with high levels of
6 psychiatric morbidity²⁶ as well as the physical harm caused and has been shown to be an important
7 risk factor for future suicide⁴. However, the processes that determine whether someone who has
8 self-harmed in the community presents to the ED may well vary between population groups and
9 geographical areas, meaning that even ED attendance data may not fully represent true variations in
10 rates of self-harm in the community between areas.
11
12
13
14
15
16

17 Implications

18
19
20 Differences in likelihood of admission between hospitals will bias estimates of rates of self-harm for
21 different areas. This has the potential to exacerbate health inequalities if it results in resources being
22 directed away from disadvantaged areas and populations on the basis of an underestimate of rates.
23 Previous research has found lower rates of admission for self-harm in English city centres compared
24 to the suburbs^{6 16}. This study suggests such findings may be partly explained by admission practices
25 resulting in an underestimate of self-harm in the inner cities when admission data is used.
26
27
28
29

30 Underestimation of self-harm rates in this study mainly affected the boroughs of Lambeth and
31 Southwark. These boroughs include areas with high levels of deprivation and substantial black and
32 minority ethnic populations and experience higher rates of adverse health outcomes²⁷ including
33 higher rates of lifetime suicidal behaviours than the national average on community surveys²⁸.
34
35
36

37 Current reliance of public health services in these boroughs on self-harm admissions data to
38 formulate their suicide and self-harm prevention strategies²⁹ risks failing to identify need in already
39 disadvantaged populations.
40
41

42 If the hospital practices driving lower admissions are more typical of hospitals serving more deprived
43 inner-city areas or otherwise under greater resource pressure, it is likely that these patterns are
44 being replicated elsewhere in the country. At a national level, London has much lower rates of self-
45 harm admissions than the English average¹⁵ however these findings provide reason to be cautious in
46 interpreting this as meaning there is truly lower underlying risk in the capital. Likewise, in other
47 settings, research findings and public health planning based on admissions data need to be alert to
48 the potential influence of such biases.
49
50
51
52
53

54
55 Routinely collected data on attendances to medical services following self-harm will always have an
56 important role in research and public health planning both in England and internationally. They
57 provide more comprehensive coverage and regular updates than research datasets can, allowing
58 variations between areas and over time to be examined. Such data also have the potential to
59
60

1
2
3 increase clinical services' understanding of the populations they serve and help them configure
4 services more appropriately. This study suggests that routine data covering ED attendances would
5 be more appropriately used for these purposes than admissions data. Such a dataset was included as
6 a "placeholder indicator" in Public Health England's Public Health Outcomes Framework (PHOF) from
7 2015¹¹ as a statement of intent to begin using such data as soon as it became available.
8
9 Unfortunately, the lack of a reliable source for the measure means it has never been produced and is
10 now earmarked for removal in the next iteration of the PHOF³⁰. The findings of this paper suggest
11 that efforts to find a way to create a reliable ED self-harm dataset should remain a priority. The
12 widespread use of electronic health records by mental health trusts and their increasing
13 incorporation into linked research databases through systems including CRIS may provide avenues to
14 do this in future, especially if linkage can be extended to ED clinical records.

17
18
19
20
21
22

23 Conclusions

24
25
26 Currently in England, as in many other countries, hospital admissions are the only comprehensive,
27 reliably coded data on the incidence of non-fatal self-harm available and so are widely used in
28 research and as a public health indicator. This analysis demonstrates that doing so may risk
29 underestimating relative rates in inner city areas and so exacerbating existing health inequalities.
30
31 Hospitals differ substantially in the proportions of individuals attending EDs with self-harm who get
32 admitted. These differences are not explained by patient characteristics, type of self-harm or
33 indicators of the severity of self-harm which suggests differences in hospital policies and practices
34 are key. ED attendances for self-harm would provide a less biased estimate of area rates for
35 comparisons hence making such data routinely available should be a public health priority.

Declarations

Ethics approval and consent to participate

Research using data within CRIS is covered by a database approval from Oxford REC C (18/SC/0372), this project was approved by the CRIS Oversight Committee (Project number 14-026). Linkage of HES data to CRIS was given approval by the NHS Health Research Authority Confidentiality Advisory Group under Section 251 of the NHS Act 2006 in 2011 (reference ECC 3-04(f)/2011).

Consent for publication

Not applicable

Availability of data and material

The datasets generated and/or analysed during the current study are not publicly available. Data are owned by a third party, the Biomedical Research Centre (BRC) Clinical Records Interactive Search (CRIS) tool, which provides access to anonymised data derived from SLaM electronic medical records. These data can only be accessed by permitted individuals with honorary contracts with SLaM from within a secure firewall (i.e., remote access is not possible and the data cannot be sent elsewhere), in the same manner as the authors.

Competing interests

The authors declare that they have no competing interests.

Funding

CP is funded by a Wellcome Trust Research Training Fellowship (grant number 105757/Z/14/Z). This paper represents independent research part funded by the National Institute for Health Research

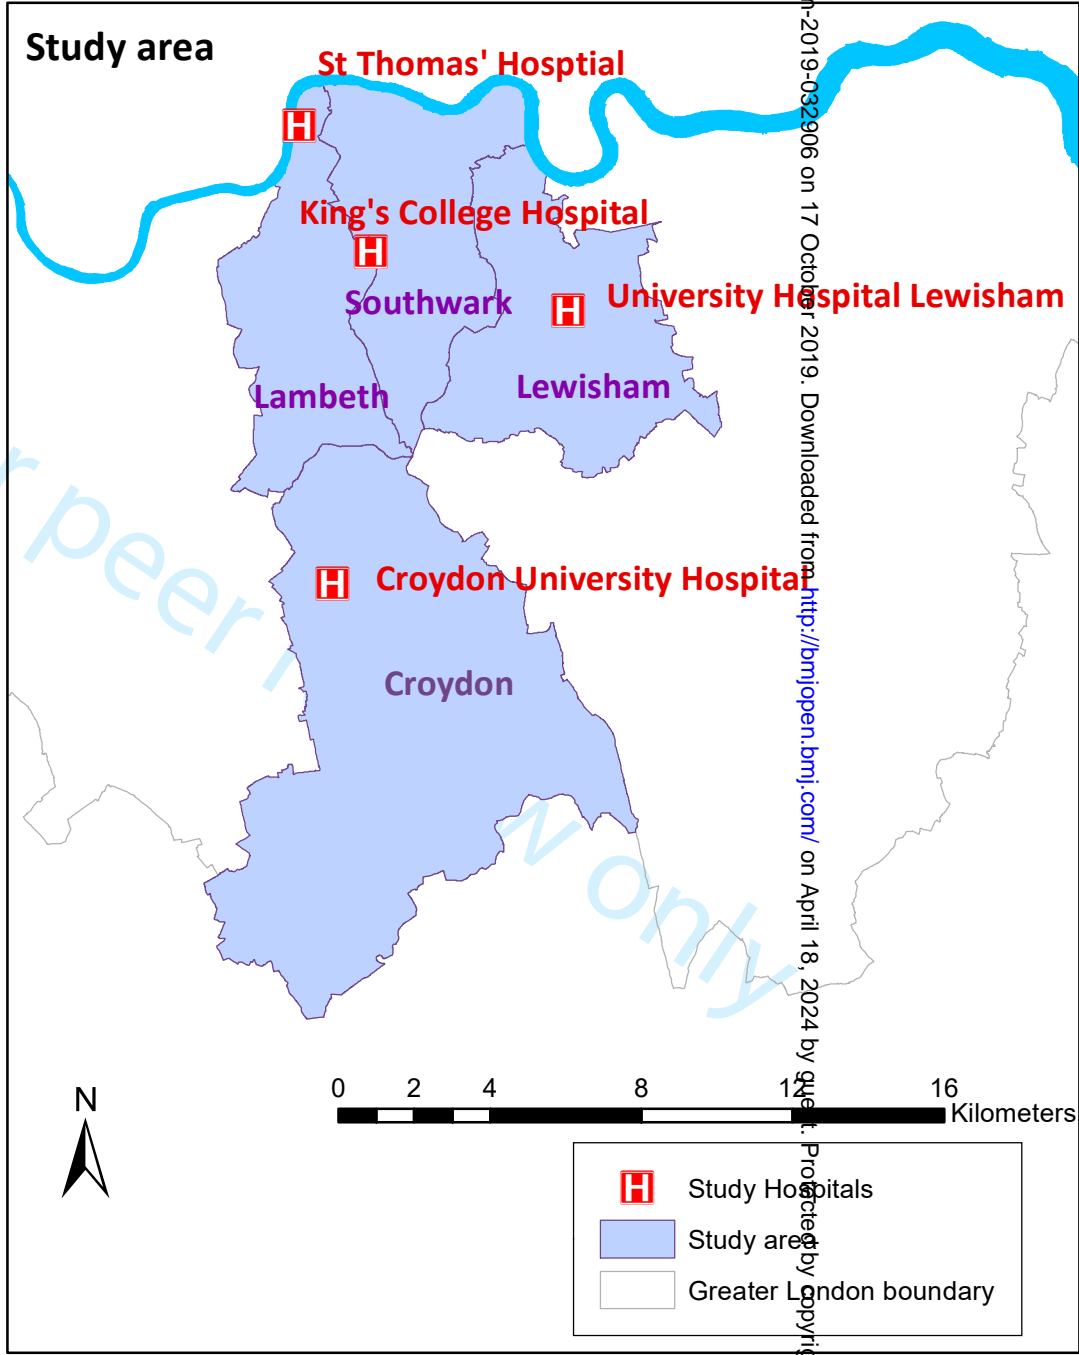

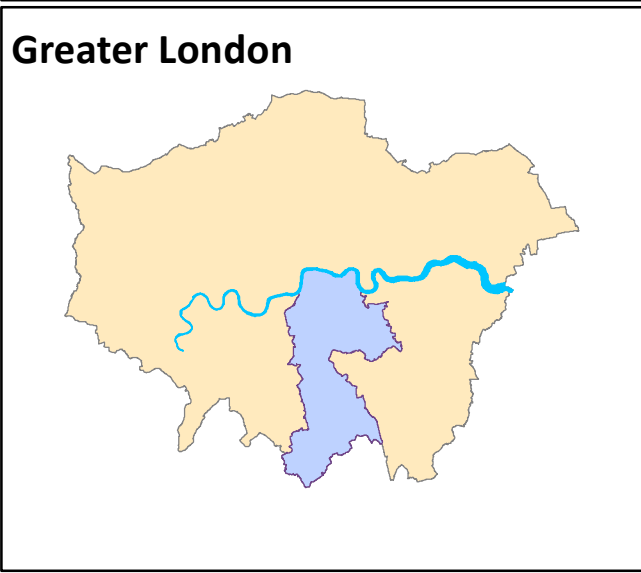

1
2
3 (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's
4
5 College London. The views expressed are those of the authors and not necessarily those of the NHS,
6
7 the NIHR or the Department of Health and Social Care.
8
9

10 Author contributions

11
12
13
14 C. Polling devised the initial research question, carried out statistical analyses, drafted the
15
16 manuscript and revised it in response to reviewer comments. I. Bakolis advised on and supervised
17
18 the statistical analyses and read and commented on the manuscript. M. Hotopf and S. L. Hatch
19
20 helped refine the initial research question, contributed to the interpretation of results and read and
21
22 commented on the manuscript.
23
24
25

26 Acknowledgements

27
28
29 We are grateful for the advice provided regarding local hospital practices by Dr Sean Cross,
30
31 consultant liaison psychiatrist in SLaM and Clinical Director of the Mind and Body Programme in
32
33 SLaM & King's Health Partners Academic Health Sciences Centre and Dr Gopinath Ranjith, consultant
34
35 liaison psychiatrist in SLaM.

STROBE Statement—Checklist of items that should be included in reports of *cross-sectional studies*

	Item No	Recommendation	Page No
Title and abstract	1	(a) Indicate the study's design with a commonly used term in the title or the abstract	1
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	2
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	3-4
Objectives	3	State specific objectives, including any prespecified hypotheses	4
Methods			
Study design	4	Present key elements of study design early in the paper	5-7
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	5
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants	5
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	5-7
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	5-7
Bias	9	Describe any efforts to address potential sources of bias	7
Study size	10	Explain how the study size was arrived at	N/a
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	7
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	7-8
		(b) Describe any methods used to examine subgroups and interactions	N/a
		(c) Explain how missing data were addressed	N/a
		(d) If applicable, describe analytical methods taking account of sampling strategy	N/a
		(e) Describe any sensitivity analyses	N/a
Results			
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed	8
		(b) Give reasons for non-participation at each stage	N/a
		(c) Consider use of a flow diagram	N/a
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders	15 (T1)
		(b) Indicate number of participants with missing data for each variable of interest	15 (T1)
Outcome data	15*	Report numbers of outcome events or summary measures	8, 15 (T1)

1			
2	Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included
3			16 (T2)
4			
5			
6			(b) Report category boundaries when continuous variables were categorized
7			N/a
8			
9			(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period
10			N/a
11	Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses
12			N/a
13			
14	Discussion		
15	Key results	18	Summarise key results with reference to study objectives
16			9
17	Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss both direction and magnitude of any potential bias
18			10-11
19			
20	Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence
21			11-12
22			
23			
24	Generalisability	21	Discuss the generalisability (external validity) of the study results
25			10-12
26	Other information		
27	Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based
28			21
29			
30			

*Give information separately for exposed and unexposed groups.

Note: An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). Information on the STROBE Initiative is available at www.strobe-statement.org.
