ABSTRACT

Objective With escalating health expenditures and increasing health needs, improving health system performance has become imperative in China and internationally. The objective of this study is to examine the efficiency of China's health system and to understand the underlying causes of the variation in efficiency across provinces.

Setting A system-wide perspective is adopted, focusing on performance in maternal health, child health and non-communicable diseases (NCDs) in the 31 provinces of mainland China during 2015.

Methods Analyses were performed using bootstrapping data envelopment technique. Health outcomes were measured by infant survival rates, maternal survival rates and healthy life years calculated only considering NCDs. Health inputs were measured using health expenditure, and density of medical personnel and hospital beds. The model also examined the impact of environmental factors on health system efficiency.

Results Due to wide-spread scale inefficiency in the country, the average bias-corrected overall technical efficiency (OTE) was 0.8022 (95% CI values ranging from 0.7251 to 0.8492). Socioeconomic status, hospitalisation rate and share of out-of-pocket expenditures were significant determinants of OTE. Nearly 60% of the provinces operated at a decreasing return to scale, meaning that a gain in efficiency could be achieved only through downsizing the scale of operation.

Conclusions Given the pervasive nature of diminishing returns across provinces, health policy makers must explore the optimum operational scale which is people-centred and focused on prevention, rather than on treatment, of diseases. Moreover, due consideration should be afforded to social determinants of health and health financing arrangements to complement health-sector based reforms and meet the ambitious goals of the Healthy China 2030 Plan.

INTRODUCTION

Health is a basic human right as well as a precondition for the economic and social development of nations.^{1 2} As an important national strategic plan for the health sector, the Healthy China 2030 Plan launched in 2016 aims to achieve a series of goals in

Strengths and limitations of this study

- Composite health outcomes consisting of maternal health, child health and non-communicable diseases were used to measure health system outputs in this study.
- A bootstrapping method was used to correct the biased efficiency scores obtained by the traditional data envelopment analysis models.
- The study only focuses on cross-sectional data and cannot reflect the change in technical efficiency over healthcare reform periods.
- Given the great variation within each province, further analysis at a lower level of geography (ie, the county level) is also necessary.

five areas, with an emphasis on improving maternal and child health and reducing premature mortality due to non-communicable diseases (NCDs).³ However, achieving these ambitious goals will not be easy, given the massive challenges within and beyond the health system. First, on the demand side, factors such as rapid population ageing, rising burden of NCDs, increasing prevalence of risk factors and changes in environmental factors will continue to put pressure on the country's health system as it tries to transform itself and meet the 2030 Healthy China agenda.¹ These increasing health needs indicate that China will struggle to meet the demands for increased health spending. Since 2008, health expenditures in China have grown, on average, by 12.8% per year, a rate substantially higher than the growth in GDP⁴; however, to what extent this trend will continue into the future remains to be seen, especially as China's economy becomes more mature and the growth rate slows down in the coming decades.^{5 6} In addition, on the supply side, changing medical practices, the legacy of uneven distribution of resources and wide disparities in population health across China

will continue to pose enormous challenge to the nation. For example, a newly born child in Beijing can expect to live an average of 83.5 years in 2015; however, this value is approximately 10 years longer than the life expectancy for a child born in Tibet.⁷ However, such health gaps between provinces seem unlikely to be narrowed by solely increasing health inputs because in places like Tibet total health expenditure as percentage of the province's GDP is already among the highest in the country, that is, 10%.⁴

Globally, it is estimated that 20%–40% of health expenditures could be saved without producing adverse health outcomes.⁸ The need for containing rising cost of healthcare vis-à-vis increasing health needs of populations in places like China and elsewhere means that improving health system efficiency has become a centre of attention across countries. However, despite the focus and priority accorded to achieving value for money in the country's health sector reform agenda, to-date there is limited evidence on health system performance assessment in China. Most of the available literature do not accurately or effectively capture the efficiency of the health system as a whole because they are largely focused on assessing institutional level technical efficiency.⁹ A few studies that examined technical efficiency at a system level, on the other hand, use healthcare activities such as outpatient visits and number of hospital admissions rather than health outcomes per se.¹⁰ However, such an approach has several limitations. First, in the Chinese context, an activity-based analysis is clearly restrictive, biased and of limited use in guiding policies and decision-making. This is partly to do with the existence of a distorted health pricing system in China, which encourages health providers to over-treat patients, and overuse drugs, tests and treatment. Moreover, an activity-based system sacrifices quality of care and leads to burnout of medical staff, and patient dissatisfaction, all of which could cause increased disputes between patients and doctors.^{11–13} In addition, an activity-based efficiency analysis also goes against the two core aspects of the country's health reform agenda, namely achieving value for money and shifting the focus away from the production of treatments to producing better health for the population.^{5,6} Several studies have used alternative health outcome-based measures, such as life expectancy, maternal mortality rate (MMR) and infant mortality rate (IMR), as their outputs of interest.^{14–16} However, these studies are outdated and use a limited range of input variables and external factors that affect the efficiency of health system in the country. Moreover, all of these studies had focused on a single outcome, but focusing solely on one outcome (such as IMR or MMR), as was done in these studies, fails to capture the broader roles that the health system plays beyond maternal and child health, such as in the prevention and control of NCDs.

The objectives of this study are, therefore, to examine technical efficiency from a holistic system-wide perspective with a focus on the improvement of child health, maternal health and NCD-related health conditions and to understand the drivers of the variation in technical

efficiency across provinces. This will help determine where the Chinese health system is doing well and where it is falling short and in turn generate a body of evidence that will guarantee the achievement of the country's 2030 Health agenda with greater efficiency.

METHODOLOGY

Traditionally, technical efficiency is measured using two major methodological approaches: parametric and non-parametric. In the case of the former, the most prominent method is stochastic frontier analysis (SFA), while data envelopment analysis (DEA) is the most common approach in the latter category. SFA allows to estimate efficiency levels and identify effects of the decision-making unit's (DMU) characteristics on efficiency scores, but it requires a functional form (or a distribution) to be imposed in the analysis.¹⁷ DEA requires no distributional assumptions. It also allows for multiple outputs and is more flexible regarding the number of DMUs required for analysis.^{18–20} Taking these advantages into account, a DEA approach was adopted in this study.

Data envelopment analysis

DEA is a linear programming mechanism used to estimate the efficiency of DMUs. The CCR model developed by Charnes, Cooper and Rhodes (CCR model)²⁰ and the BCC model developed by Banker, Charnes and Cooper (BCC model)²¹ are the two extensively used models within the DEA framework. Technical efficiency scores obtained using the CCR model represent overall technical efficiency (OTE). These scores can be decomposed into pure technical efficiency (PTE) and scale efficiency (SE) using the BBC model as expressed in the following equation.²¹

$$\text{OTE} = \text{PTE} \times \text{SE}$$

Output orientation and returns to scale

A DEA model can be either input-oriented or output-oriented. Under input orientation, the efficiency scores correspond to the largest feasible proportional reduction in inputs for given outputs; under output orientation, the efficiency scores correspond to the largest feasible proportional expansion in outputs for given inputs.²⁰ In this study, an output-oriented model was adopted due to the desirability of maximising health outcomes given that input levels in the health system are usually fixed in the short run.^{22,23}

Returns to scale (RTS) is an important concept in production function as it explains long-run relationships between inputs and outputs. The CCR model operates under the assumption of constant return to scale (CRS), which implies that a unit increase in input levels will result in a proportional increase in outputs. If the global technology is not operating under a CRS, technical efficiency levels estimated using a CRS model are generally inconsistent. A variable return to scale (VRS) model, developed as part of the BBC, addresses this shortcoming by allowing

a disproportionate change in output levels as input levels change by one unit. Accordingly, an increasing return to scale is achieved when greater increases in the outputs are attained, while a decreasing return to scale (DRS) is achieved when a unit change in input leads to a disproportionately lower increase in the output level. Hence, given the importance of global technology in the DEA and the absence of solid evidence on the nature of RTS in this study area, a two-part returns-to-scale test as proposed by Simar and Wilson²⁴ was performed.

According to the result of the test, the null hypothesis of CRS was rejected at a 99% level of significance. Therefore, a VRS was used to assess the performance of different provincial health systems in the promotion of health.

Bootstrapping DEA and truncated bootstrapped regression

Traditional DEA models are more sensitive to the selection of inputs and outputs and neglect the effects of non-discretionary factors that influence the production function, which make the efficiency scores biased. Hence, a bootstrapping DEA model proposed by Simar and Wilson was used to estimate bias-corrected technical efficiency scores at the first stage. A truncated bootstrapped regression was used in the second stage to identify external factors that may influence the efficiency scores. The analyses were performed in Stata V.15 using user-developed commands proposed by Badunenko and Mozharovskiy.^{25 26} Based on the default settings, 1000 repetitions and 2000 repetitions had been used in the first and second stage analysis, respectively.

Patient and public involvement

Our analysis was based on publicly available aggregated secondary data. Hence, the study did not directly involve patients or the public at large.

Data and variables

Input and output variables

The Chinese health system is made up of a hybrid system, whereby both private and public delivery of health services and healthcare payment systems coexist. There are mainly two health insurance systems in operation in China: the medical insurance scheme designed for urban employees and the system available for rural residents and those who are not in the labour force. The latter includes children and the elderly in urban areas as well as rural residents who are covered through the new rural cooperative medical schemes. Both schemes operate throughout the country and are similar across the provincial health system.

To examine health system efficiency at the provincial level, we have included all the 31 administrative areas in mainland China. These provinces form the DMUs in our analysis. Variables for analysis were selected based on evidence from similar previous studies and availability of data.^{27–30} For the input portion, the number of medical personnel per 1000 residents, the number of hospital beds per 1000

residents and the total health expenditure per capita was used. Medical professional category includes physicians (namely general practitioners and specialists), but does not include nurses, pharmacists or other medical staff. It is recognised that physical measures such as the number of equivalent full-time staff may be a better indicator of availability of human resources for health, but unfortunately such data are not available. Hospital bed was used as a proxy for capital investment. Total health expenditure per capita is the sum of public and private health expenditure as a ratio of total population, and it covers the spending on all kinds of health providers for health service delivery.

For the output portion, the health outcomes were measured by IMR, MMR, and the mortality and the years lost due to disability (YLD) caused by NCDs, in view of several reasons. First, each measure basically represents the health status of three key population groups that can benefit from effective health systems. It is reported that premature mortality from NCDs by 2030 can be reduced by one-third if more effort is committed and certain targets for risk factor interventions are achieved in China.³¹ Two-thirds of the avoidable maternal and infant mortalities were attributed to health worker-related factors, and 10.2% were attributed to poor supply factors.³² The main causes of maternal mortality are all amenable to interventions at a health system level and are highly relevant in China.^{33 34} Second, these conditions represent major public health concerns in China. NCDs are responsible for 87% of total deaths in China³¹, and significant health gaps still exist in child health and maternal health across provinces. Additionally, all three indicators represent major areas of focus in the Healthy China 2030 Plan and are of high policy significance.

In the DEA model, outputs are understood to represent 'more is better'. To meet these criteria, as what had been done in previous studies,^{27 30} IMR was converted into infant survival rates (ISR) ($ISR=1000-IMR$), and MMR was converted into maternal survival rates (MSR) ($MSR=100\,000-MMR$). NCDs mortality and YLD was converted into NCDs-based healthy life years (HLY_NCDs), whereas only mortality and morbidity caused by NCDs were considered when calculating HLY. The concept of HLY has emerged as one of the more commonly used health status measures that incorporates both mortality and morbidity.^{35 36}

Factors such as disposable income per capita, educational attainment, urbanisation rate, financing protection (represented by the percentage of out-of-pocket (OOP) in total health expenditure) and healthcare service use pattern measured by admission rate were considered in the second stage analysis. These factors were selected based on evidence from similar previous studies and availability of data.^{27–30 37} Given only 31 observations in our analysis, to keep a limited number of independent variables in the analysis, a composite socioeconomic status (SES) index was constructed using principal component analysis based on disposable income per capita, educational attainment and urbanisation.

Table 1 Summary of statistics of the variables

Variable	Units	Mean	SD	Minimum	Maximum
Outputs					
ISR	Per 1000 live births	994.69	3.36	984.00	997.77
MSR	Per 100 000 live births	99983.68	17.52	99899.10	99997.70
HLY_NCDs	Years	77.25	2.50	71.86	82.93
Inputs					
Health expenditure	CNY per capita	3258.34	1297.42	2103.71	8453.14
Medical personnel	Per 1000 residents	2.25	0.42	1.70	3.90
Hospital bed	Per 1000 residents	5.13	0.63	4.02	6.37
Environmental variables					
Disposable income	CNY per capita	21912.26	8988.54	12254.30	49867.20
Urbanisation	Percentage	56.64	12.89	27.74	87.60
Education attainment	Years	8.59	1.34	4.17	12.16
Percentage of OOP in total health expenditure	Percentage	29.00	6.49	5.71	36.89
Admission rate	Percentage	14.43	3.00	7.30	21.40

ISR, infant survival rates; MSR, maternal survival rates; HLY_NCDs, NCDs-based healthy life years; OOP, out-of-pocket.

Data source

Multiple data sources were employed. The data source of each variable is listed as follows.

- ▶ China Health and Family Planning Statistical Yearbook 2016: MMR, medical personnel density, hospital bed density.
- ▶ China Maternal and Child Annual Health Report: IMR.
- ▶ National Health Reports 2016: Health expenditure per capita, percentage of OOP in total health expenditure.
- ▶ Chinese Center of Disease Control and Prevention: NCDs mortality and YLD.
- ▶ China Statistical Yearbook 2016: disposable income per capita, educational level, urbanisation rate and admission rate.

RESULTS

Descriptive statistics

Table 1 presents a descriptive overview of the variables used in this study. The ranges for inputs and outputs are quite wide. For example, the ISR across provinces vary between 984 per 1000 live births and 998 per 1000 live births, namely, a baby's risk of death in the first year of life in Tibet is nearly six times greater than that in Guangdong and Beijing. Regarding the HLY_NCDs, an 11.07-year gap exists between provinces. The lowest was Tibet (71.86 years) and the highest was Shanghai (82.93 years). Similar patterns are apparent for inputs, especially health expenditures. The health expenditure per capita ranged from 2103.71 Chinese Yuan (CNY) to 8453.14 CNY, which suggests that the level of health system input is quite heterogeneous across provinces.

Efficiency estimates

Table 2 summarises the bias-corrected OTE, PTE and SE estimates obtained using an output-oriented DEA model for the 31 provinces of China. As mentioned earlier, the estimates were generated using VRS technology following results of RTS test. The bias-corrected PTE for the country as a whole was 0.9947, meaning that overall the country's health system has been operating highly efficiently. The mean level of SE is, however, much lower, that is, approximately 0.8653 (suggesting scale inefficiency level of 13.47%). As a consequence, the bias-corrected OTE was 0.8022 (95% CI 0.7251 to 0.8492).

Table 2 further suggests that only 13 of the 31 provinces (or 41.9% of the total) operated at the most productive scale size (MPSS). The remaining 18 provinces (58.1%) operated at a DRS which means that a gain in efficiency can only be achieved by scaling down operational size.

Figure 1 portrays a deeply heterogeneous picture in terms of bias-corrected OTE across 31 provinces. It clearly shows five tiers in technical efficiency levels by geographic locations. Tianjin, Guangdong and Hainan in the east, and Yunnan and Tibet in the west had the highest biased-corrected OTE values, ranging from 0.9186 to 0.9486, whereas Inner Mongolia, Sichuan, Qinghai and Xinjiang in western China had the lowest biased-corrected OTE, ranging from 0.6441 to 0.7458, along with Liaoning, Heilongjiang, Shandong and Hubei. Regions of high level economic development, such as Beijing, Shanghai, Zhejiang and Jiangsu, do not rank high in biased-corrected OTE, yielding values of lower than 0.80, which indicates the high level of scale inefficiency. The Kruskal-Wallis test confirmed that the biased corrected

Means statistical inference cannot be provided for some provinces due to too few bootstrap replications where those observations lie within the bootstrap frontier. DRS, decreasing returns to scale; MPSS, most productive scale size; OTE, overall technical efficiency; PTE, pure technical efficiency; SE, scale efficiency; RTS, returns to scale.

Figure 1 Overall technical efficiency across provinces.

OTE scores differ but not significantly among groups, and biased corrected PTE scores significantly differ among groups based on their location ($p < 0.10$ for OTE, and $p < 0.001$ for PTE). Generally, the provinces located in the east outperformed all other regions, with a mean biased corrected OTE of 0.8380, followed by those in the west and in the centre. North-eastern provinces performed the worst. In contrast, eastern provinces were the least efficient in PTE, but the gap was negligible.

Figure 2 portrays the association between SE and health inputs. Accordingly, the most scale efficient provinces tend to have lower health worker and hospital bed densities. The means of the number of medical personnel and hospital beds between scale efficient provinces and scale inefficient provinces were significantly different ($p < 0.001$).

Table 3 presents the results of the truncated bootstrapped regression analysis, which estimated the effect of environmental factors on OTE at the provincial level. The results suggest that OTE levels were negatively and significantly affected by SES index, percentage of OOP in total health expenditure and hospital admission rate.

DISCUSSION

This study investigated TE and SE of the provincial health system in China and the role of environmental factors in

influencing both SE and PTE with respect to ISR, MSR and HLY_NCDs. The work is of particular policy significance given the finite health resources and continually rising health needs.

Our results indicate that bias-corrected PTE was generally high in all provinces (ie, 0.9947). However, given the relatively high levels of scale inefficiency (ie, 13.47%), the bias-corrected OTE level, on average, was rather low (ie, 0.8022). Moreover, the OTE was quite heterogeneous across provinces. Provinces in the high economic development corridor in the eastern China tended to have a relatively high OTE, while provinces in the less-developed regions performed less efficiently, especially the north-eastern provinces, which displayed the lowest OTE. Some of the well-off provinces also experienced high inefficiency in their local health systems. For example, Beijing, Shanghai, Jiangsu and Zhejiang scored bias-corrected OTE values of less than 0.80, which meant that considerable resources invested in these regions did not generate the desired impact on health outcomes. Nevertheless, of even greater concern was that less-developed provinces with poor health outcomes, such as Xinjiang, Heilongjiang and Qinghai also suffered poor OTE in the production of health.

In our study, the low OTE of health systems across provinces was generally caused by a high level of scale inefficiency

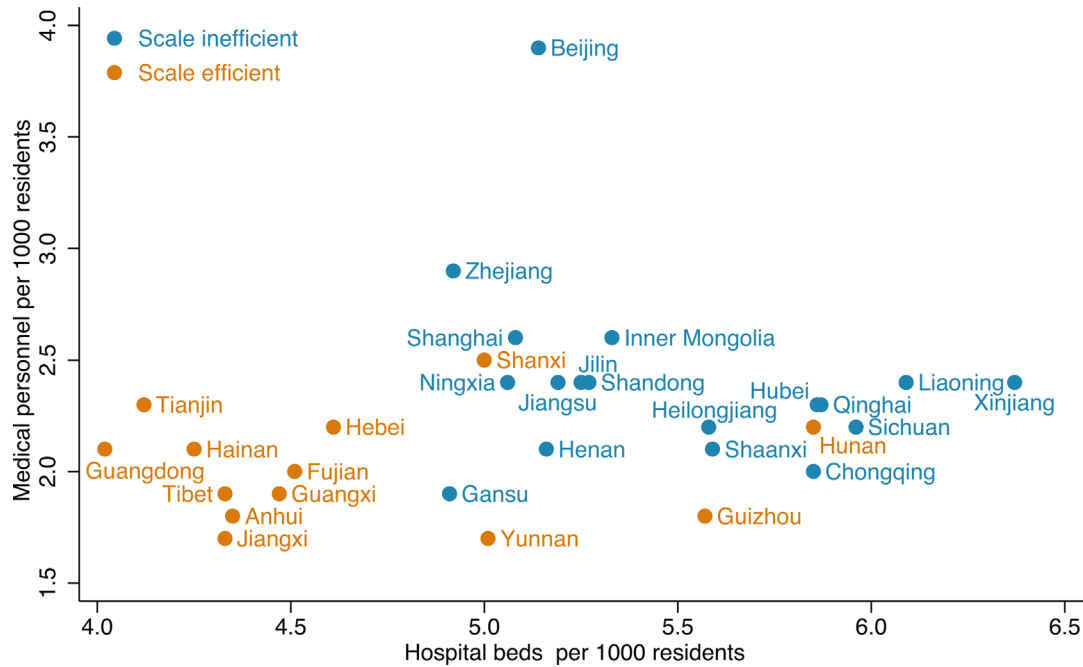

Figure 2 Association between scale efficiency and health inputs.

observed across provinces. The results indicated only 41.9% of the provinces operated at the MPSS, while 58.1% exhibited DRS, which implied that an increase in inputs can only generate a smaller increase in health outcomes. In general, hospital bed density played an important role in the SE of provinces. If the hospital bed density was greater than 5.0 per 1000 residents, the chances for a province to be scale inefficient were greater. This reflected the so-called flat-of-the-curve medicine phenomenon, referring to a level of intensity of care that provides no incremental health benefit.³⁸ Coincidentally, an increasing number of studies have shown diminishing returns of health system inputs on health outcomes. For instance, Asandului *et al* revealed that 26 of 30 European countries under scrutiny exhibited DRS, and only four countries presented a scale efficient system.³⁹ Cetin and Bahce reported that technical efficiency would be increased by using lower resources for 11 OECD countries with health systems characterised by DRS.⁴⁰ Another study showed that reducing health input levels can help improve efficiency in Central Asian health systems.⁴¹ This also holds in the case of China. Zhang *et al* revealed that the reduction of SE is an objective law when they investigated

health system efficiency in China as a whole compared with other countries.¹⁰

Variables for analysis were selected based on evidence from similar previous studies and availability of data. Given the heterogeneous OTE of health systems across provinces in China, Simar and Wilson’s two-stage procedure was employed to examine and better understand the drivers behind this variation.²⁴ Several findings are highlighted here. First, the results suggested that the higher the percentage of OOP in total health expenditures is, the greater the inefficiency level is, which implies that a public financing-dominated care system is more suited to create a more efficient production of health. Consistent with the findings of González *et al*,⁴² they reported that the public share in health expenditures is positively associated with improved health system performance. Sun *et al* found a 1% point increase of the share of social security spending could improve health system efficiency by 1.9%.⁴³ It is intuitive because a public financing arrangement entails people having equal access to health services and improves their utilisation of health resources that have already been equipped. In recent years, the Chinese

Table 3 The effects of the environmental variables on overall technical efficiency					
	Observed coef.	Bootstrap std. err.	P>z	Percentile (95% CI)	
Socioeconomic status index	-0.004	0.002	0.005	-0.007	-0.002
Percentage of OOP in total health expenditure	-0.007	0.003	0.035	-0.013	-0.001
Admission rate	-0.016	0.007	0.013	-0.030	-0.004

OOP, out-of-pocket.

government has acknowledged that the current financial risk is high in China, and further efforts to improve public financing have been stressed. According to the Healthy China 2030 Plan, the percentage of OOP in total health expenditures is planned to be reduced from 29% in 2015 to 25% by 2030.³

Second, in our study, the negative association of admission rates with efficiency implied that a resource-intensive hospitalisation service use was harmful to health system efficiency. Our results are similar to those of Chowdhury and Zelenyuk which reported that outpatient–inpatient ratio is a significant driver of efficiency.³⁷ If limited health resources are not rationally allocated and used to maximise health outcomes, low technical efficiency would occur. In China, over the past 37 years, that is, since the ‘opening-up policy’, total health expenditures have been rapidly growing, with an annual growth rate of 11.7%.⁴ One underlying cause of the unprecedented escalation of health expenditures is a rapidly expanding public hospital system, with hospital beds being a major component. Hospitals account for 54% of China’s total health expenditures,⁴ which was more than the OECD average level of 38%.⁴⁴ As the saying goes, ‘A hospital bed built is a bed filled’.⁴⁵ Accordingly, the number of hospital beds in China doubled from 1.2 million to 2.2 million from 1980 and 2000, and reached 5.3 million in 2015.⁴⁶ Currently, the Chinese health delivery system features a highly hospital-centred care system with a primary health system that is marginalised as well as fragmented.^{47 48} The level of hospital bed density in China now exceeds some OECD countries such as Canada, the UK, the USA and Spain.⁴⁴

SES is one of the most powerful predictors of health indicator, and addressing several components of SES (ie, income poverty and low education) could be important for population health improvement.⁴⁹ In our study, we observed that provincial health system inefficiency was positively associated with provincial socioeconomic index. The results of current study were inconsistent with that of Ramin *et al*, Achoko *et al* and de Cos and Moral-Benito.^{28–30} In terms of maternal and child health, many studies have documented that maternal literacy plays a crucial role in improving life-saving services for mothers and children.^{50 51} Moreover, it has been proved in many studies that economic level (eg, per capita GDP) was positively associated with health system efficiency.^{29 52} However, the effect of urbanisation on health is not clear-cut in China. While urban life offers individuals the benefits of access to improved healthcare, nutrition and sanitation facilities, it also exposes them to air pollution, risk of traffic hazards and behavioural risks associated with changing diets and physical activity patterns.⁵³

Finally, given the high level of scale inefficiency in China, it is imperative for health policy-makers to explore the optimum operation scale of health systems and rationalise health systems’ supplies, rather than blindly increase health resource investment to achieve better population health. It

is well known that health could be greatly improved by real-locating resources from interventions that are not cost-effective to those that are more cost-effective but not fully implemented for health systems.^{22 38 42}

Limitations and suggestions for future research

Our analysis is not without limitations. First, it focused only on health system efficiency using cross-sectional data. Future research can use multiple data points and examine how efficiency has changed in the country over time, especially examining the impact of healthcare reforms on health system efficiency and productivity. Second, we have only looked at health system efficiency at a provincial level, mainly due to data limitations. However, further analysis focusing on the county level is also necessary given variations in health inputs and outputs within each province. Third, in our analysis the primary DMUs (ie, provinces) are assumed to be independent of each other, which may not be the case. Hence, a spatially sensitive efficiency model, such as those developed for SFA,⁵⁴ can be considered in future studies.

CONCLUSIONS

Improving health system efficiency is crucial for achieving value for money and improving population health across China and internationally. Given the pervasive diminishing returns in health systems across China, health policy-makers must shift the focus on treating people to preventing diseases, and exploring the optimum operation which ensures that resource allocation is people-centred. Moreover, social determinants of health and health financing arrangements should also be fully considered and a target for policy-makers to realise the ambitious goals of the Healthy China 2030 Plan.
