ABSTRACT

Objectives To analyse the prevalence and determinants of turnover intention (TI) among primary health workers (PHWs) in China to provide evidence for improving retention measures.

Design Systemic review and meta-analysis.

Data sources Four English-language databases (PubMed, EMBASE, Cochrane Library, PsyNFO) and three Chinese databases (CNKI, CSPD, CBM) were searched up to October 2019.

Eligibility criteria Eligible studies were observational or descriptive studies conducted in mainland China. The prevalence of TI among health workers and related factors had to be explicitly reported in each included study.

Data extraction and synthesis Data were extracted by one author and reviewed independently by two other authors. For each factor analysed by a meta-analysis, the factor was required to be the same across different studies, and at least three studies had to include it. The quality of studies was assessed using the Newcastle–Ottawa Scale and heterogeneity was evaluated using the I² statistic.

Results We identified 16 cross-sectional studies investigating a total of 37,672 PHWs. The prevalence of TI was 30.4%. Subgroup analysis revealed that the highest prevalence was observed in the community primary healthcare institutions and the eastern provinces of China. Meta-analyses indicated that 21 factors were significantly associated with TI, including demographic factors (gender, age, education, marital status), job characteristic factors (title, work seniority, remuneration, social status, organisational affiliation, work stress) and job satisfaction factors (learning and training opportunity, interpersonal relationship, work condition and environment, and so on).

Conclusion This study highlights the problem of TI among PHWs in China. Efforts should be made to improve conditions in both work-related areas and areas outside of work. Policymakers should continue to improve reward systems, the construction of infrastructure and promotion systems, and pay more attention to PHWs’ lives outside of work and meet their living needs.

INTRODUCTION

Primary healthcare (PHC) addresses the majority of a person’s health needs throughout their lifetime. The Declaration of Astana declared that strengthening PHC is the most inclusive, effective and efficient approach to enhance people’s physical and mental health and social well-being. Primary health workers (PHWs) are direct providers of PHC, and their quantity directly determines the quantity, quality and outcomes of PHC. These services should be provided with compassion, respect and dignity by health professionals who are well trained, skilled, motivated and committed.

However, primary health institutions are facing significant labour shortages worldwide, not only in low-income and middle-income countries but also in developed countries. In China, PHC services including basic medical and public health services, are provided by community health centres and stations in urban areas and by township health centres and village clinics in rural areas. These four types of PHC institutions constitute the essential part of China’s three-tertiary healthcare delivery network. PHWs working inside include doctors, nurses, public health workers and administrative staff, most of them have to play multiple roles. Currently, PHC institutions are all facing the problem of staff turnover, aggravating the shortage of the health workforce, which has become one of the significant obstacles to strengthening China’s primary healthcare services.
management and maintenance of the current workforce. \textsuperscript{11} Turnover intention (TI) is defined as the probability that an employee will leave his or her job within a specific period\textsuperscript{15}; TI is considered to be one of the best predictors of turnover behaviour. \textsuperscript{15-16} Previous studies have explored the factors that influence the TIs of PHWs. A variety of factors have been identified, such as demographic factors, \textsuperscript{7} 17-25 job satisfaction, \textsuperscript{18} 20 22-25 work stress, \textsuperscript{15} 18 25 burnout, \textsuperscript{23} 26 quality of work-life, \textsuperscript{21} interpersonal communication\textsuperscript{27} and violence from patients. \textsuperscript{26} While these factors have been definitely linked with TI, some researchers have focused on factors outside of work. Han and Humphreys\textsuperscript{29} found that key factors of community integration influence overseas-trained doctors’ decision to stay in or leave a rural community in Australia; Stewart \textit{et al}\textsuperscript{27} reported that community satisfaction is a crucial predictor of intent to leave among rural and remote registered nurses in Canada; and Chao \textit{et al}\textsuperscript{12,13} demonstrated that there is a significant correlation between work–family conflict and the TI of PHWs in Taiwan and Guangdong.

In China, many empirical studies have been conducted. However, there is no consistent conclusion on the prevalence and determinates of TI among PHWs in China. Furthermore, most of them were published in Chinese, only a few studies on TI and risk factors for PHWs have been published in international journals, and no related systematic reviews have been found in either Chinese or English. Therefore, this study aims to examine the prevalence of TI and identify the related factors among PHWs in China by conducting a systemic review and meta-analysis.

**METHOD**

**Literature search**

This systematic review and meta-analysis were performed following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines.\textsuperscript{30,31} A systematic search of the literature was conducted up to October 2019 using four English-language databases (PubMed, EMBASE, Cochrane Library, PsycINFO) and three Chinese databases (CNKI, CSPD and CBM). No limits were applied for language and publication dates of coverage. The search strategy was based on a combination of “(Turnover Intention, or Departure Intention, or Demission Intention, or Leave Intention, or intent to leave), AND (Primary, Community, Rural, Country-side, District, Basic, Fundamental or Grassroots), AND (Health worker, Health officer, Health Manpower, Health Personnel, Medical Personnel, Medical worker, Medical staff, Doctor, Physician, or Nurse) and (China, or Chinese)”. References of the retrieved studies were also checked and screened. The full search strategy can be found in the online supplemental table S1.

**Study eligibility**

Eligible studies were published studies that reported the prevalence and related determinants of TI among Chinese PHWs. The eligibility criteria included the following: (1) types of studies: original cross-sectional studies (those presenting non-original data, such as reviews, editorials, opinion papers or letters to the editor, were excluded); (2) types of participants: Chinese PHWs; (3) types of risk factor: demographic factors, job characteristic factors and job satisfaction factors; and (4) types of outcome measures: the prevalence of TI and related factors reported in the study.

Eligibility assessment was conducted to screen the titles, abstracts and full texts of the identified studies by two reviewers independently. Disagreements on which studies should be included or excluded were resolved by full group consensus.

**Data extraction**

A piloted form referred to the Cochrane Effective Practice and Organization of Care Review Group data collection checklist,\textsuperscript{32} was used to extract relevant data from the included full-text studies. The following data were extracted: author, publication year, location where the study was carried out, participants, sample size, number of cases, assessment tools, prevalence of TI and related factors. Data extraction was conducted by one author and reviewed independently by two other authors, with disagreements resolved by discussion until consensus was reached. The inter-rater reliability for title screening between two authors was 96.15%, and for abstract screening was 94.74%. The full inter-rater reliability result can be found in the online supplemental table S2.

**Quality assessment**

The quality of studies was assessed using a modified Newcastle–Ottawa Scale,\textsuperscript{33} as recommended by the Cochrane Collaboration.\textsuperscript{34} Studies received scores based on the design-specific sources of bias, methods for selecting participants, exposure measures, outcome variables and methods to control confounders.\textsuperscript{35} The total score was 7 points, and all the included studies were grouped according to their scores, which were categorised as good (6–7), moderate (3–5) and poor (1–2). Specifically, a study with a sample size of less than 1000 was regarded as having poor representativeness of the sample (score=0, otherwise=1); a cross-sectional study with a response rate lower than 80% or without reporting a response rate was considered a poor-quality study (score=0, otherwise=1). Meanwhile, if statistical methods used in the study were exact, we considered statistical test to be appropriate (score=1, otherwise=0), even if there was no further multivariate analysis. Three authors independently scored all included studies, with disagreements resolved by discussion until consensus was reached.

**Data synthesis and statistical analysis**

The primary outcome in this review was the difference in the prevalence or relative risk of TI among different groups. The prevalence of TI was estimated as the total number of TI cases divided by the total number of PHWs...
participating in the study. It was assessed via single-arm analysis. We compared the difference in TI between PHWs from different regions and institutions by subgroup analyses. The secondary outcome of this study was the association between factors and TI among PHWs in the form of the OR. Each factor analysed by a meta-analysis, required related variables in the questionnaire to be the same in different studies, which meant that it was feasible to merge the factor into two groups; meanwhile, at least three studies related to each factor had to be included in the meta-analysis. When the meta-analysis was performed, the significance of the pooled OR was determined by the Z-test. Heterogeneity was estimated by the Q statistic and evaluated using the I² statistic. A fixed-effect model was used to compute the summary risk estimate if there was no heterogeneity among the studies, whereas a random-effects model was used when heterogeneity existed (I² ≥50%). Publication bias was evaluated using Egger’s test. All statistical analyses were performed using Stata V.13.0 and RevMan V.5.3. A two-tailed p value of <0.05 was considered to be statistically significant. We referred to the Meta-analysis of Observational Studies in Epidemiology guideline. If it was infeasible to make a quantitative synthesis and conduct a meta-analysis, a narrative approach and descriptive statistics were used by grouping studies that reported the same factors, and to compare their associations with the TI of PHWs.

**Patient and public involvement**

Patients and the public were not involved in this study.

**RESULTS**

A total of 455 records were identified through our initial database search (PubMed: 13, Embase: 14, Coherence: 6, PsycINFO: 0, CNKI: 124, WAN FANG Data: 270, CBM: 28). After duplicate records were removed, 208 records were screened based on title and abstract. Eighty-seven articles were included in the full-text review. Among these, 63 articles were eliminated due to a lack of original data. Three articles were eliminated due to inappropriate study designs. Five articles were excluded because of missing data on risk factors for TI. Ultimately, 16 studies were included in this study. No additional studies were obtained after the references of all 16 retrieved articles were checked. The study selection process is shown in figure 1.

### STUDY CHARACTERISTICS

Table 1 presents the main characteristics of all 16 studies. These studies were all cross-sectional and performed in 24 provinces of China between 2011 and 2019. The selected studies included 37,672 participants, with a median sample size of 1073 (range 127–16,157). Five studies were conducted in eastern China, four in central provinces and four in the western region. Four studies were conducted in urban areas, eight in rural areas and four in both areas.

Thirteen studies used a dichotomous question to measure TI (Do you want to leave your job? Yes/No) and three studies used scales. All studies reported the prevalence and related factors of TI among PHWs.

Forty-seven factors were extracted from 16 included studies (online supplemental table S3). It included three groups: 7 demographic factors, 22 job characteristic factors and 18 job satisfaction factors. The average quality score of the 16 included studies was 5.25 of 7 points, indicating a moderate research quality.

TI, turnover intention.

Prevalence of TI among PHWs

Table 2 shows the prevalence of TI among PHWs in China. The pooled prevalence was 30.4%. The highest prevalence was 54.3% reported by Gu et al, whereas Zhang reported the lowest prevalence of 8.0%. The subgroup analysis by region showed that the highest prevalence was observed in the eastern China (37.6%), followed by central regions (31.9%) and western regions (23.2%). According to work setting, the highest prevalence occurred among PHWs working in the community, followed by rural PHWs working in towns and villages. With respect to sample size, the prevalence of TI was higher in studies having a sample size $<10^3$ (35.5%) than in those with a sample size $\geq10^3$ (25.5%). High heterogeneity was observed across the included studies due to the inconsistent research sites, regions and objects.
Factors related to TI among PHWs

All studies reported demographic factors or job characteristic factors and determined their associations with the TI of PHWs. Moreover, six studies explored the effects of job satisfaction factors, and 19 factors were feasible for inclusion in the meta-analyses. Egger’s linear regression tests on a natural logarithm scale of OR found no evidence of publication bias for the studies included in meta-analyses (online supplemental table S5).

Demographic factors and TI

The meta-analysis of demographic factors was based on 15 cross-sectional studies (figure 2). Gender (male vs female, OR: 1.23, age (younger vs older, OR: 1.47) and marriage status (unmarried vs married, OR: 1.16) were significantly associated with TI in PHWs, which showed that the PHWs with higher risks of TI were men, were younger, had a higher education, were unmarried and worked in the remote region. But education (low-education vs high-education, OR: 0.78) was not statistically significant.

Job characteristic factors and TI

Job characteristic factors were examined in nine studies (figure 3). Job title (low-title vs high-title, OR: 1.11), work seniority (short vs long, OR: 1.17), organisational affiliation (strength vs others, OR: 0.85) and work stress (high vs low, OR: 3.14) were significantly associated with the TI of PHWs, which presented that the PHWs with higher risks of TI were those with shorter work seniority, higher work stress and longer working hours. However, occupation (doctor vs nurse, OR: 1.05) was not statistically significant.

Job satisfaction factors and TI

Six studies explored the association between job satisfaction factors and TI (figure 4). Overall job satisfaction (satisfied vs dissatisfied, OR: 0.15), promotion and individual development space (satisfied vs dissatisfied, OR: 0.19), interpersonal relationships (satisfied vs dissatisfied, OR: 0.20), keep busy and fulfilling (satisfied vs dissatisfied, OR: 0.39), sense of accomplishment (satisfied vs dissatisfied, OR:0.16), income satisfaction (satisfied vs dissatisfied, OR: 0.33), work condition and environment (satisfied vs dissatisfied, OR: 0.19), level of attention by leaders (satisfied vs dissatisfied, OR: 0.20), the competence of my manager in making decisions (satisfied vs dissatisfied, OR: 0.18), the confidence of my manager in making decisions (satisfied vs dissatisfied, OR: 0.21) were significantly associated with the TI of PHWs. The results showed that PHWs who were dissatisfied with their job had significantly higher risks of TI.

The remaining 28 exposures were analysed for their associations with the TI of PHWs under a narrative approach. In the demographic factors group, PHWs who work in remote regions and who have lower remuneration and social status were found to have significantly higher risks of TI. No significant associations were found between TI and the nation. In addition, the associations between TI and major in clinical medicine are inconclusive.

Among job characteristic factors, seven were significantly associated with high risks of TI, including lower individual remuneration levels at the local level, more severe emotional exhaustion, more severe flattening of affect, more participation in public health service, longer working hours, no career planning and lack of insurance. No significant associations were found between TI and qualified to practice, re-employment after retirement, turnover experience, career identity, influence on family life, patient trust. In addition, the associations between TI and living condition are inconclusive.

Regarding job satisfaction factors, PHWs who are unsatisfied with work stability, the chance to try their own methods of performing their job, the chance to do something that makes use of their abilities, work support, policies practice and income fairness were found to have significantly high risks of TI. However, no statistically significant associations were found between TI and the satisfaction with the

DISCUSSION
Principal findings
This systematic review presents an overall prevalence of TI (30.4%) among Chinese PHWs which indicated that three of ten PHWs have TI. However, this finding is almost two times higher than that of some high-income countries. A study conducted in England showed that only 11.8% of primary care doctors had high TI. A survey including 23159 nurses from 10 European countries showed that 9% of all these nurses intended to leave their profession, varying from 5% to 17% among countries.

Another survey performed among 2263 physicians in America reported that 18.4% of them intended to leave their practice. A study conducted in Canada reported that 17.2% of registered nurses intended to leave their current nursing position. Meanwhile, the prevalence of TI was lower than in some low-income and middle-income countries, such as Ghana, Iraq, South Africa and the Philippines.

The subgroup analysis indicated the variation in the prevalence of TI among regions. The possible explanations for this variation might be the difference in the level of social and economic development and the workplace.

Figure 2  Forest plots of demographic factors.

scientific research atmosphere or learning and training opportunity.46–48
better work environment. It attracts many PHWs to move away from primary care practice.58 As rural PHWs, they usually settled down in rural areas, lacking access to urban hospitals compared with peers in the urban community.

This study extracted a broad scope of 47 related factors and determined their associations with the TI of PHWs, identifying a total of 31 demographic, job characteristic and job satisfaction risk factors.

Five demographic risk factors were determined to have significant associations with the TI of PHWs, which showed that the PHWs who were men, were younger, had a higher education, were unmarried and worked in the remote region with high risks of TI. Some of these findings are in line with studies performed in South Africa, the Philippines, Canada, Saudi Arabia, Ghana and the Netherlands.17 20–22 25 57 However, Bonenberger et al20 and Labrague et al57 showed that the association between gender and the TI of PHWs was not statistically significant. It can be concluded that different types of PHWs have unique characteristics of TI. Accordingly, we can sum up the high-risk population among PHWs. For example, the TIs of an unmarried young practitioner who received full medical training could be expected to be higher than a married older practitioner with limited training. The policymakers and medical institutions managers should formulate or adjust retention measures based on these characteristics.

According to job characteristic factors, we concluded that PHWs who had shorter work seniority, higher work stress and longer working hours had significantly higher risks of TI. All of these findings are consistent with prior studies. Nevertheless, some
Figure 4  Forest plots of job satisfaction factors.
findings are inconsistent with prior studies. Remuneration was found to be statistically significant in the review, which is consistent with Almalki et al., but Labrague et al. reported an insignificant association between remuneration and TI. Occupation and level of the medical institution were not significantly associated with TI in the review, in accordance with Warnelink et al. and Labrague et al. However, some studies reported the opposite results. In addition, seven factors identified in the review were never or rarely reported in other countries, including title, social status, participation in public health service, insurance, career planning, emotional exhaustion or flattening of affect and authorised personnel, which were found to have significant associations with a high risk of TI among PHWs in China. Among these factors, ‘emotional exhaustion’ and ‘flattening of affect’ are measures of mental health status. In recent years, the mental health status of the health workforce has deteriorated due to increasing work stress and violence. Some studies also found that mental health has significant associations with job satisfaction and job burnout. In the context of COVID-19, all PHWs have been mobilised to fight the epidemic, which will undoubtedly have a negative impact on their mental health status. The risk of TIs caused by mental health problems cannot be ignored.

There is a significant inverse association between job satisfaction and TI. In this review, we found that low overall job satisfaction reported significantly higher risks of TI among PHWs, which is in line with Bonenberger et al., Warnelink et al. and Delobelle et al. Furthermore, most of the job satisfaction factors are also significantly associated with the TI of PHWs. However, these specific job satisfaction factors have rarely been reported in previous studies.

Notably, compared with previous studies focused on the family factors, our study did not find relevant evidence on family factors in China such as: community satisfaction, numbers of dependent family members or family commitments.

Limitations and strengths

To our knowledge, this is the first systematic review (including meta-analysis) to determine potential risk factors for TI among Chinese PHWs. Our findings present an overview of the current evidence from mainland China. One strength of this review is that it estimated the prevalence of TI among Chinese PHWs based on a large sample size with a total of 16 cross-sectional studies and 37,672 participants. Another strength is that it determines the associations of a broad scope of potential risk factors. Limitations exist in this systematic review. Significant heterogeneity among the individual studies was found when the subgroup analysis and the part of meta-analysis were performed. The main reason is the heterogeneity between different studies in research region and research site. Due to the limitation and shortage of the current studies, it is hard to conduct a further study.

Literature gaps

Therefore, it can be concluded that there are many facets of the TIs among PHWs that need to be explored. First, the differences in TI by occupation within the different regions or institutions need to be explored. Second, there is insufficient research on the interaction effects of demographic and other factors. More research is needed to better represent and understand how two or more determinants work together to impact the TIs of PHWs. Third, the impact of family factors on TIs requires more attention. Last but not least, the relationship between public health services and the TIs of PHWs in the context of the COVID-19 is a worthy research issue.

CONCLUSION

The analysis highlights the problem of TIs among PHWs in China. There is a significant association between demographic factors, job characteristic factors, job satisfaction factors and TIs. Policymakers should take into account all aspects of human needs that influence PHWs’ intentions to stay. As illustrated by the Global Strategy on Human Resources for Health, it is particularly important to find pragmatic solutions to overcome deeply entrenched rigidities in public sector rules and practices that hinder the adoption of adequate reward systems, working conditions and career structures for health workers, with appropriate levels of flexibility and autonomy. Therefore, efforts can be made to improve factors both at work and outside of work. In terms of work factors, policymakers should continue to improve reward systems, the construction of infrastructure and promotion systems. Outside of work, authorities should pay more attention to PHWs’ lives and meet their living needs to increase their willingness to work and live in communities, towns and villages. We also suggest that particular attention be given to PHWs working in the community or the eastern region of China to reduce their TIs by implementing evidence-based health workforce policies.

Contributors RH and YM conceived this research project. JL and RH developed the search strategy and RH searched the databases. JL, BZ, NZ and RH selected the studies. RH designed and executed the analyses, interpreted the findings, wrote the first draft, revised subsequent drafts, and prepared the manuscript. YM and WHZ revised drafts of the manuscript.

Funding This research was funded by the Major Project of National Social Science Fund of China: Research on big health putting prevention first and construction of healthy China (grant number 17ZDA079).
