ABSTRACT

Introduction Lumbar spinal stenosis (LSS) is a common lumbar degenerative disease in the elderly, usually requiring surgery if conservative treatment fails. Microscopic decompressive laminectomy (MDL) and percutaneous endoscopic decompressive laminectomy (PEDL) have been widely used to treat LSS. This study aims to provide a protocol for the evaluation and comparison of the efficacy, safety and applicability between MDL and PEDL.

Methods and analysis We will search for randomised controlled trials (RCTs) comparing MDL and PEDL for treating LSS from inception to December 2019 in the following databases: PubMed, The Cochrane Library, Web of Science, Embase and China Biology Medicine. The quality of included studies will be assessed using the risk of bias tool recommended by the Cochrane Handbook 5.2.0. Subsequently, a meta-analysis will be performed using RevMan 5.3 software.

Ethics and dissemination Given the nature of this study, no ethical approval will be required. The protocol will be disseminated via a peer-reviewed journal.

PROSPERO registration number CRD42020164765.

INTRODUCTION

Lumbar spinal stenosis (LSS) occurs predominantly in the elderly, with an incidence rate of 10.3%–11.2% in individuals aged over 70 years. It is divided into central spinal stenosis, lateral crypt stenosis and neural root canal stenosis. LSS is mainly caused by congenital spinal dysplasia or acquired factors, such as bone hyperplasia, disc herniation, ligament hypertrophy, spinal trauma, lumbar spondylolisthesis and iatrogenic LSS. A typical symptom of LSS is neurogenic intermittent claudication; in severe cases, patients may also show symptoms of cauda equina syndrome, which requires emergency surgery.^{1–4}

Strengths and limitations of this study

- This study will first systematically evaluate the efficacy, safety and applicability of microscopic decompressive laminectomy and percutaneous endoscopic decompressive laminectomy.
- The research results will provide a reference for clinicians to choose an appropriate minimally invasive surgery for lumbar spinal stenosis.
- This study provides improved clinical applicability and comparability of derived results through subgroup analysis.
- The results of this study may change and need to be updated when new high-quality randomised controlled trials are reported.
- We only include English and Chinese literatures, which may lead to a selection bias.

The gold standard procedure for LSS is open decompressive laminectomy, but in recent years, minimally invasive decompressive laminectomy (MIDL) procedures such as microscopic decompressive laminectomy (MDL) and percutaneous endoscopic decompressive laminectomy (PEDL) using smaller incisions have become more popular due to reportedly satisfactory results.^{5–8} A number of randomised controlled trials (RCTs) comparing MDL and PEDL for LSS have been published,^{6–10} but high-quality systematic reviews (SRs) are lacking. Therefore, this study uses a meta-analysis method to systematically evaluate and compare the efficacy, safety and applicability between MDL and PEDL provide a basis for spinal surgeons to choose an appropriate surgical procedure.

METHODS

Inclusion criteria

Type of study

Only RCTs comparing MDL with PEDL for treating LSS will be included in this SR. Patients should be randomly assigned into MDL and PEDL groups. The language of the literature will be limited in English or Chinese.

Participants

This study includes patients diagnosed with LSS according to the criteria defined by the North American Spine Society.¹ Patients with lumbar surgery history, epidural injection history, specific or non-specific infection and tumour will be excluded.

Interventions

The MDL procedure is briefly described as follows: after confirming the target level, a small skin incision (3–4 cm) is made approximately 1.5 cm lateral to the spinous process, placing the tubular retractor on a series of tubular dilators through the intermuscular space for retraction. Following this, laminectomy, flavectomy and partial facet resection are performed to achieve spinal canal decompression with the aid of a microscope. Further, contralateral decompression can be performed by tilting the operating table and microscope.^{6 11–13}

The PEDL procedure is briefly described as follows: a working sheath and working-channel endoscope are inserted through a 1 cm incision, 0.5–1 cm lateral to the spinous process. Instruments for laminectomy are inserted through the working channel. An endoscopic laminectomy is identical to a microscopic laminectomy but under continuous saline irrigation. The surgical field is visualised using a monitor system.^{6 8 9}

Cointervention, conventional open techniques using loupe magnification and lumbar decompression combined with lumbar interbody fusion will be excluded.

Outcomes

The primary outcomes will include lower back and leg pain intensity measurement via a Visual Analogue Scale (VAS) or a Numerical Rating Scale (NRS) within 2 weeks after surgery. Oswestry Disability Index (ODI) and European Quality of Life-5 Dimensions (EQ-5D) score will be collected within 1 year after surgery. Secondary outcomes will include operation time, intraoperative blood loss, postoperative drainage and serum creatine phosphokinase level at 2 days after surgery, and adverse events (eg, dural tear, nerve root injury, incomplete decompression, reoperation and epidural hematoma).

Data sources

We will search PubMed, The Cochrane Library, Web of Science, Embase and China Biology Medicine databases from inception to December 2019.

Search strategy

We will use the following English search terms to build our search strategy: ((spin* OR lumb* OR “nerve

root canal” OR “lateral recess” OR “lateral crypt”) AND stenosis*) OR “intermittent claudication” OR LSS OR DLSS OR LSCS OR LCS) AND (decompressi* OR minimally OR micro* OR laminectom* OR MISS OR full-endoscop* OR endoscop*) AND (random* OR blind* OR “controlled clinical trial*”). Besides, we will search for Medical Subject Headings (MeSH) terms as follows: (“Spinal Canal”[Mesh] OR “Lumbar Vertebrae”[Mesh] OR “Spinal Diseases”[Mesh] OR “Constriction, Pathologic”[Mesh] OR “Spinal Stenosis”[Mesh] OR “Lumbar Stenosis, Familial”[Supplementary Concept] OR “Spinal Osteophytosis”[Mesh] OR “Spondylosis”[Mesh]) AND (“Decompression”[Mesh] OR “Decompression, Surgical”[Mesh] OR “Minimally Invasive Surgical Procedures”[Mesh] OR “Microsurgery”[Mesh] OR “Endoscopes”[Mesh] OR “laminectomy”[Mesh]) AND (“Randomized Controlled Trials as Topic”[Mesh] OR “Randomized Controlled Trial”[Publication Type] OR “Controlled Clinical Trial”[Publication Type] OR “Controlled Clinical Trials as Topic”[Mesh] OR “blindness”[Mesh]) (see online supplemental file).

Study selection and data extraction

After selecting studies according to the above-mentioned inclusion criteria, two independent reviewers will read the full texts and extract the data. Disagreements between reviewers will be resolved by consultation with a third researcher. If the data included in the study are incomplete or the data are reported in the form of a graph, we will contact the author via email to obtain the original data. If the author cannot be contacted or refuses to provide the data, we will remove the study from the meta-analysis and give a statistical description in the Results section.

Quality assessment of included studies

The quality of the RCTs will be assessed using the risk of bias (RoB) tool recommended by the Cochrane Handbook V.5.2.0 (Cochrane Collaboration, London, UK). This assessment is performed considering six aspects: (1) random sequence generation; (2) allocation concealment; (3) blinding of participants and outcome assessors; (4) incomplete outcome data; (5) selective reporting and (6) other bias. The RoB in each domain is classified as low risk, high risk or unclear. If the RoBs of the studies included in the meta-analysis differ, we will conduct a hierarchical analysis based on the RoB to show readers the different results under different RoBs.

Subgroup analysis

To reduce the effect of clinical heterogeneity between studies on the conclusions of the meta-analysis and to observe whether the clinical efficacy and incidence of complications in the two procedures are different in different areas of stenosis (central or lateral recess stenosis, foraminal stenosis), scopes of decompression (unilateral or bilateral decompression) and levels of

decompression (single-level or multilevel decompression), a subgroup analysis will be conducted.

Data synthesis and analysis

We will use RevMan 5.3 software (Cochrane Collaboration) to perform the meta-analysis. If more than two studies include primary outcomes, a meta-analysis will be conducted. Weighted mean difference or standard mean difference with 95% CI will be calculated for continuous data. The Higgins I^2 test will be used to assess heterogeneity, with a significance level set at 25%. A fixed-effect model will be used in the case of low heterogeneity ($I^2 \leq 25\%$); otherwise, a random effects model ($I^2 > 25\%$) will be used.¹⁴ Meta-regression (if more than 10 studies are included) or sensitivity analysis will be applied to explore the source of heterogeneity. If the I^2 value of the combined results is greater than 75%, we will abandon the meta-analysis and only give a general statistical description of the research results.¹⁴

The minimal clinically important difference (MCID) is defined as 'the smallest difference in a score that is considered to be worthwhile or important'.¹⁵ Thus, if the meta-analysis results reach or exceed this score, the results will be considered as meaningful and worthwhile. The MCID scores of the primary outcomes are regarded as follows: VAS, 3.0^{13 16}; NRS, 2.0¹⁷; ODI, 12.0¹³ and EQ-5D, 0.24.¹⁶

Finally, a funnel plot will be constructed following Egger's test to evaluate publication bias.

Quality of evidence

The grading of recommendations, assessment, development and evaluation (GRADE) will be used to assess the quality of evidence for all outcomes, including the following: RoB, inaccuracy, inconsistency, indirectness and publication bias. The results of assessment will be graded under four levels: very low, low, moderate and high levels.¹⁸

Patient and public involvement

Patients and the public were not involved in the design or planning of this SR protocol.

DISCUSSION

Evidence-based medicine has shown that compared with conventional open decompression laminectomy, MIDL is more accurate, with less intraoperative bleeding, less post-operative pain, faster body function recovery and shorter hospitalisation duration.^{19 20} However, because of some limitations of MIDL (eg, difficulty in instrument manipulation, poor visualisation and long learning cycle), which results in inadequate decompression, nerve damage and prolonged operation time, the success rate of MIDL is still controversial.^{6 20 21} Although MIDL has many issues to be resolved, with continuous improvement of equipment and the gradual maturation of surgical technology, the advantages of MIDL over the conventional open

decompressive laminectomy are increasing, and it is expected to become the new technical standard.^{20 22–24}

We will perform this study in strict accordance with the Cochrane Handbook for Systematic Reviews of Interventions, and report in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines. We want to conduct this SR to comprehensively evaluate MDL and PEDL and compare them, and provide some suggestions for its reasonable and effective clinical application.

TRIAL STATUS

- Preliminary searches: started.
- Piloting of the study selection process: not started.
- Formal screening: not started.
- Data extraction: not started.
- RoB assessment: not started.
- Data analysis: not started.

ETHICS AND DISSEMINATION

Because this is an academic review of the published literature, no ethical approval will be required. This protocol will be submitted to a recognised journal for publication and to presentations at national and international conferences.
