ABSTRACT

Objective This study aimed to assess magnitude and associated factors of suicidal ideation and attempt among people with epilepsy attending outpatient treatment at primary public hospitals, northwest Ethiopia using suicide module of World Mental Health Survey initiative version of the WHO, composite international diagnostic interview.

Design Multicentre-based cross-sectional study was used.

Setting Data were collected using face to face interview from patients with epilepsy who attended outpatient treatment at primary public hospitals at northwest Ethiopia.

Participants Adult patients with epilepsy (n=563) who came to attend outpatient treatment during the study period were included in the study using systematic random sampling technique.

Outcome measures Suicidal ideation, suicidal attempt and factors associated with suicidal ideation and attempt.

Results The overall magnitude of suicidal ideation and attempt was 26.5% and 12.6%, respectively. Being woman adjusted OR (AOR)=1.68, 95% CI 1.09 to 3.23, living alone (AOR=2.4, 95% CI 1.47 to 3.92), divorced/widowed/ (AOR=2.2, 95% CI 1.09 to 7.8), family history of suicidal attempt (AOR=2.53, 95% CI 1.34 to 4.79), depression (AOR=3.18, 95% CI 1.85 to 5.45), anxiety (AOR=2.92, 95% CI 1.68 to 5.09), comorbid medical illness (AOR=2.60, 95% CI 1.17 to 5.82) and poor social support (AOR=2.35, 95% CI 1.26 to 4.40) were statistically associated with suicidal ideation. Depression (AOR=4.87, 95% CI 2.56 to 9.28) living alone (AOR=2.66, 95% CI 1.62 to 5.41), family history of committed suicide (AOR=2.80, 95% CI 1.24 to 6.39), taking medication for mental illness (AOR=2.17, 95% CI 1.06 to 4.46), hazardous alcohol use (AOR=2.10, 95% CI 1.05 to 4.23) were statistically associated with suicidal attempts at a p value <0.05.

Conclusion This study showed that the magnitude of suicidal ideation and attempt was high among people with epilepsy. Being woman, living alone, having depression and anxiety, single, divorced/widowed in marital status, family history of suicidal attempt and poor social support were statistically associated with suicidal ideation. Having

Strengths and limitations of this study

- This is a multicentre study to assess the magnitude of suicidal ideation and suicidal attempt among patients with epilepsy attending treatment at primary healthcare settings.
- The study identified various factors associated with both suicidal ideation and suicidal attempt.
- Study used standardised tools to assess both suicidal ideation, suicidal attempt and independent variables with both patient interview (primary data) and chart review (secondary data).
- Recall bias could be a limitation to this study particularly for questions related to an outcome variable suicidal ideation.
- Since the data were collected during a time when there was fear of COVID-19 pandemic, patients with epilepsy particularly with other chronic physical comorbid condition were thought to send their relatives to collect their monthly medications and this might have an effect on the current results.

depression, living alone, family history of suicide attempt, hazardous alcohol use and drug taking for mental illness were statistically associated with suicidal attempt. Based on the findings of this study early screening, detection and management of suicide were recommended in people with epilepsy.

BACKGROUND

Suicide is fatal act that represents the person's wish to die. There is complex process that involves a series of pathways and mechanisms that starts from initiation of suicidal ideation to planning for days, weeks or even years before acting, while others take their lives seemingly on impulse without premeditation.^{1 2} The Diagnostic and Statistical Manual of Mental Disorders defines suicidal ideation as a thinking about, considering or making

plans for suicide and suicidal attempt a deliberate, self-destructive act with a clear expectation of death that is non-fatal.³

The burden of suicide constitutes a serious public health issue in the world.⁴ According to a global estimate from the WHO, around 800 000 people die due to suicide annually. This is corresponding to an age-standardised suicide rate—of around 11.5 per 100 000 people—a figure equivalent to someone dying in every 40s.⁵ The worldwide burden of suicide is estimated to increase to 2.4% by 2020 year, and the rate of death due to suicide will be one person every 20s.⁶

Suicidal acts result from a complex interaction of biological, psychological, sociological, cultural and environmental factors.⁷ From the biological and psychological conditions, people with mental and neurological illness such as epilepsy are vulnerable. Epilepsy is a chronic disorder of the brain and is one of the most common serious neurological disorders worldwide with no boundary to age, race, social class, nationality or geographical location.⁸ It affects more than 50 million people in the world.⁹ The prevalence of people with epilepsy (PWE) among the general population varies across the countries from 0.5% to 5%.¹⁰ The community-based epidemiological study in Ethiopia reported that PWE were 5.2/1000 population.¹¹ Epilepsy affects relationship with family and friends, employment, school, leisure activities and results in social and economic consequences. Each of these effects may lead to high magnitude of comorbid psychiatric illness among PWE.¹²

PWE are at higher risk for suicide when compared with the general population. For example, the life-time prevalence of suicidal ideation among PWE that was reported 25% is higher than people without epilepsy 13%.¹³ The suicidal rate reported that people with temporal lobe epilepsy (TLE) 6%–25% times when compared with 1.4%–6.9% in the general population.¹⁴ This indicated that suicide is common comorbid psychiatric illness among PWE.¹⁵ Similarly, different study results showed that PWE are high risk for suicidal ideation and attempt.^{16 17} The estimated lifetime prevalence of suicidal attempt among PWE ranged from 3.3% to 14.3%,¹⁸ whereas about 38% of patients with epilepsy had suicidal ideation.¹⁷ The estimated prevalence of suicidal ideation and attempts was 45.2% and 28.6%, respectively.¹⁹ Around 11% of deaths among PWE are due to suicide and the suicide attempt increase the chance of later completing suicide by 38%.²⁰ Results from meta-analysis indicated that the pooled prevalence for suicide ideation (24 studies) and suicide attempts (18 studies) was 23.2% and 7.4%, respectively.²¹ Centres for disease control and prevention report that the suicide rate among people with epilepsy is 22% higher than the general population with 16.89/100 000 people with epilepsy compare with 13.84/100 000 in the general population.²²

The greatest risk factors of suicidal ideation and attempts among people with epilepsy is psychiatric disorders including depression and other mental disorders.²³

Poor social support, drug treatment for mental illness, those who had psychiatric comorbidity such as comorbid depression, low economic status and unemployment were also reported risk factors from prior studies.²⁴ Other factors included poor interpersonal relationship, stigma related to the epilepsy and pre-existing psychiatric illness.^{25–27} In addition, early age onset of epilepsy, anti-epileptic drug polytherapy, high seizure frequency and duration of epilepsy were factors found to significantly associated with suicidal ideation and attempt.^{13 28}

Despite this burden and consequences, there is limited study done on suicide ideation and attempt among people with epilepsy in eastern Africa as well as in Ethiopia. There was a single study conducted in Addis Ababa Ethiopia in 2014 in Saint Amanuel Specialized Mental Hospital the only specialised mental hospital in Ethiopia that provide. The suicidal ideation and attempt among people with epilepsy reported in the study was 29.8% and 14.1%, respectively, with various significantly associated risk factors.²⁴ However, there are limited data in the country particularly suicide among patients with epilepsy in settings where psychiatry service limited and or not available including in patients attending primary hospitals. Therefore, this study aimed to assess the magnitude and associated factors of suicidal ideation and attempt among people with epilepsy. This would help for future integrated intervention and it would be an input of information for policymakers to institute intervention strategies.

METHODS

Study design and setting

Institutional based cross-sectional study was conducted from 15 March to 1 May 2020, at central Gondar zone primary public hospitals in four primary hospitals named, 'Wogera', 'Dembia', 'Delagi' and 'Aykel' primary hospitals, which are located in the northwest part of Ethiopia.

Study participants

All adult patients (age ≥18 years), who had been clinically diagnosed with epilepsy and who were at outpatient treatment at Delagi, Wogera, Dembia and Aykel primary hospitals were study participants. Patients who were unable to communicate and seriously ill at the time of the data collection were not included.

Patient and public involvement

No patients were involved.

Sampling

The adequate number of samples required for this study were 569, determined by using single population proportion formula ($n_i = \frac{(Z\alpha/2)^2 p(1-p)}{d^2}$). By using a 14.1% prevalence of suicidal attempt²⁴ and setting 3% tolerable margin of error, 95% CI and 10% non-response rate. A systematic sampling method was used to select study participants from selected hospitals during the study

period using the number of patients following treatment per month as a sampling frame in each of the hospitals. Study participants were recruited based on proportional allocation from each primary hospital.

Data collection and measurements

Data were collected by face to face interviews using a structured questionnaire and through patients' chart reviews. Suicidal ideation and attempt were assessed by items that were adopted from module of World Mental Health survey initiative version of the WHO composites international diagnostic interview in which suicide was studied and validated in Ethiopia both at clinical and community settings with internal consistence Cronbach's $\alpha=0.97$.^{29 30} Its Cronbach's α in current study was 0.85. Standardised and validated measurements in low-income countries including Ethiopia were used to assess other variables including Fast alcohol assessment tool (FAST) for hazardous alcohol use,^{31 32} Hospital Anxiety and Depression Scale for depression and anxiety^{33 34} and Kilifi stigma scale (KSS) for perceived stigma.³⁵ Social support was collected by Oslo-3 item of Social Support Scale. It is 3-item questionnaires commonly used to assess social support and it had been used in several studies. The sum of score scale was ranging from 3 to 14, which had three categories: poor support 3–8, moderate support 9–11 and strong support 12–14.³⁴ The internal consistence, Cronbach's α of Oslo-3 items in the current study was 0.81. Eight trained Bachelors of Science in psychiatric nurses collected the data using the Amharic version questionnaires.

Data processing and analysis

The data were checked for completeness and consistency and entered to Epi-Data V.4.6.0.2 and was exported to SPSS V.20 for analysis. The binary logistic regression model was used. Bivariate and multivariate logistic regression analysis was performed to identify associated factors to outcome variables. All variables with a p value less than 0.20 at bivariate analysis were entered into the multivariate logistic regression model. A p value of <0.05 was considered statistically significant, and the adjusted OR with 95% CI was calculated. Goodness of model fitness was checked by using Hosmer-Lemeshow test.

RESULTS

Sociodemographic characteristics of respondents from a total of 569 samples, 563 participants were included in the study with response rate of 98.9%. The median age of respondents was 29 and IQR was 23–36 years. The majority of them 57.5 % (324) was men. Regarding living arrangement of participants, 63.7 % (359) were living with family, the majority of participants 65.2% (367) was orthodox by religion and 33.7% (190) was farmers as shown below in table 1.

Clinical, psychosocial and substance-related factors of respondents

Majority, (68.2% (384)), of participants reported the age onset of epilepsy when they were 18 years and above.

Table 1 Sociodemographic characteristics of people with epilepsy of central Gondar zone primary public hospitals, northwest, Ethiopia, 2020 (n=563)

Variable	Category	Frequency (n=563)	Percentage
Sex	Male	324	57.5

	Urban	213	37.8

Nearly half, (44.0% (248)), of the respondents had 1–6-year duration of treatment while 59.9% (337) had up to 5-year duration of illness. More than three-fourth, 79.6% (448), of participants were taking one antiepileptic medication. Out of the total study participants, 21.1% (119) and 29.8% (168), were found to have anxiety and depression, respectively, whereas 8.75 %³⁶ had comorbid medical illness. Family history of suicide indicated that about 12.4% (70) had family history of suicide attempt and 7.3%³⁷ had family history of committed suicide. Regarding social support, 42.6% (240) had moderate social support. Out of the total participant, 66.4% (374)

Hazardous alcohol use	Yes	78	13.9
	No	485	86.1

had not perceived stigma and 27.7% (156) of participants were current substance use as shown below in [table 2](#).

Magnitude of suicidal ideation and attempt among people with epilepsy

The lifetime magnitude of suicidal ideation and attempt in this study was 26.5% (149) with (95% CI 23.1 to 30.4) and 12.6% (71), with (95% CI 9.9 to 15.5), respectively. Among the respondents who had a suicidal ideation, 59.1% (88) had suicidal ideation within the last 12 months and 15.8% (89) had planned to commit suicide in a lifetime ([table 3](#)).

Factors associated with suicidal ideation among people with epilepsy

In bivariate logistic regression analysis, variables like being woman, living alone, single, divorced/widowed, family history of suicidal attempt, family history of committed suicide, depression, anxiety, ever substance use, taking medication for mental illness, comorbid medical illness, perceived stigma, hazardous alcohol use and poor social support were significantly associated with suicidal ideation. In multivariate logistic regression analysis, variables like being woman, living alone, family history of a suicidal attempt, anxiety, depression, being single, divorced/widowed, comorbid medical illness and poor social support were statically significant for suicidal ideation with p value less than 0.05. To identify the effect of each variable, a multicollinearity statistics test was checked and the variance inflation factors of each variable were a range of 1.03–2.54 ([table 4](#)).

Factors associated with suicidal attempt among people with epilepsy

In bivariate logistic analysis, variables like living alone, being divorce/widowed, family history of committed suicide, family history of mental illness, depression, taking medication for mental illness, comorbid medical illness, perceived stigma and hazardous alcohol use were statically significant to suicidal ideation at p value less than 0.2. In multivariate logistic analysis, variables like living alone, family history of committed suicide, depression, taking medication for mental illness and hazardous alcohol use were statically significant at p value less than 0.05 ([table 5](#)).

DISCUSSION

The current study showed that the lifetime magnitude of suicidal ideation was 26.5% with (95% CI 23.1 to 30.4). Regarding magnitude, the finding of current study was

in line with study carried out in Brazil, which reported a prevalence of 28.9%,³⁸ a study from Egypt that showed 23.5% of suicidal ideation³⁹ and in Addis Ababa Ethiopia where the prevalence of suicidal ideation was 29.8%.²⁴ It was also similar with a pooled prevalence result of a meta-analysis that reported 23.2% of suicidal ideation.²¹

However, the result of this study was lower than study conducted in Bosnia and Herzegovina, where suicidal ideation was indicated 38%.¹⁷ A study of suicide among patients with epilepsy in Havana city of Cuba has shown in 45.2% of suicidal ideation¹⁹ whereas in Malaysian study, it was reported 33.75%⁴⁰ with study result from Brazil indicating 36.7%.⁴¹ The possible reason for the discrepancy

might be the study participants in which the current study used only outpatients, but the study done in Bosnia and Herzegovina and Cuba used both inpatient and outpatients. The other reason might be the sample size where 5 013 180 153 samples were used in Bosnia and Herzegovina, Havana city of Cuba, Malaysia and Brazil, respectively, which were smaller compared with the current study participants (n=563). The difference in study design used might also be another reason for this variation since this study used an institutional based cross-sectional study but a prospective cohort study was used in the Havana city of Cuba, case-control study in Malaysia and community-based case-control study in Brazil.

On the other hand, the finding of current study was higher than studies done in the USA, which reported a suicidal ideation prevalence ranging from 8% to 11.9%^{37 42} and a Canadian study that reported a 12.7% suicidal ideation.⁴³ Similar studies conducted in different countries including Poland,⁴⁴ Rio de Janeiro, Brazil,⁴⁵ Republic of china⁴⁶ and Nigeria⁴⁷ reported 10%, 13.3%, 14.3% and 20.0% suicidal ideation, respectively, which were lower than the current study. The possible reasons for the difference might be variation in study design and the difference in assessment tools used. In the USA, study suicidal ideation was assessed by using the ninth items of beck depression inventory, the same suicidal assessment tool was used in the Poland and Do Rio de Janerio, Brazil studies. The time frame in which the suicidal ideation occurred might be another reason for the difference in the prevalence and many of the previous studies used the current suicidal ideation but the current study considered the lifetime suicidal ideation. The difference in sample size could also be another possible reason for the discrepancy in which the sample sizes ranged from 25 to 251 in the previous studies compared with the 563 participants of the current study.

The magnitude of the suicidal attempt in this study was 12.6% with (95% CI 9.9 to 15.5). This study result was in line with study results from Croatia,⁴⁸ Brazil,⁴¹ Egypt³⁹ and in Addis Ababa Ethiopia²⁴ with a reported prevalence of 14.1%, 12.1%, 11.5% and 14.1%, respectively.

However, the finding of this study was lower than studies conducted in Havana city of Cuba 28.6 %, ¹⁹ Bosnia and Herzegovina 18 %¹⁷ and in Brazil 21.2%.³⁸ The possible reasons for the discrepancy might be the difference in study participants. For example, only patients with TLE were the study participants in the Brazil study, whereas both inpatient and outpatients were used in studies conducted in the Bosnia-Herzegovina and Cuba. The difference in study design could be also another reason. A prospective cohort study was used in Bosnia and Herzegovina, whereas the current was a cross-sectional study.

On other hand, the finding of this study was higher than the study conducted in Iran¹³ and Asia²¹ which was 5.5% and 7.4% attempted suicide, respectively. This discrepancy might be due to sample size differences where only 200 individuals participated in the Iran study. It was also

lower than a meta-analysis study result (7.4%), which was based on pooled prevalence from 18 different studies²¹

Multivariate logistic regression models showed that being woman, living alone, single and divorced/widowed in marital status, depression, anxiety, family history of suicidal attempt, comorbid medical illness and poor social support were significantly associated with suicidal ideation.

In this study, women had about 1.68 times higher suicidal ideation than men. Similar result was reported from studies conducted in the USA⁴² and Poland.⁴⁴ The possible justification for this association might be due to culture influence in which women may not discuss their problems with others as men, and it might be due to women having greater vulnerability to other psychosocial

stress. The other possible justification might be related to depression in which women are two times more likely to have depression as compared with men.¹ This is evidenced by a result from meta-analysis study that consists of studies from 30 countries indicating that point prevalence of depression was significantly higher in women.⁴⁹

Participants who lived alone were 2.4 times more likely to have suicidal ideation than those who lived with family. This finding is supported by studies conducted in Washington³⁷ and a previous study done in Addis Ababa Ethiopia.²⁴ This might be due to the fact that those who lived alone had no a nearby individual (family) that they could communicate and share their problems and that could lead to increased hopelessness and suicidal ideation. This had also been strengthened by the result regarding marital

status in which being single and divorced and or widowed were found to be more vulnerable to suicidal ideation though it does not mean these group of participants live alone. This result was supported by a study conducted in Poland.⁴⁴ This might be because of lack of social support and significant other to share emotional and other psychosocial burdens due to various environment stresses that predispose to depression with manifestations including hopelessness and suicidal behaviours.

Regarding to family history of a suicidal attempt, participants who had family history of an attempt were 2.53 times more likely to have suicidal ideation than participants who had no family history of a suicidal attempt. This result was consistent with studies conducted in Croatia,⁴⁸ Cuba,¹⁹ and previous study in Addis Ababa Ethiopia.²⁴ The possible justifications might be from a non-genetic perspective like having a common life style, learnt behaviour, faced with similar family stress and environmental related factors and may also be due to biological predisposition.

Respondents who had depression were 3.18 times more likely to have suicidal ideation than respondents who had no depression. This result was supported by study done in Washington,³⁷ Canada,⁴³ Bosnia and Herzegovina,¹⁷ Poland,⁴⁴ Brazil,³⁸ Malaysia,⁴⁰ Korea,³⁶ Nigeria⁴⁷ and Addis Ababa Ethiopia.²⁴ Many of this previous studies justified that the presence of depression is highly associated with suicidal ideation. The possible reason might be due to the direct effect of depression, which makes individuals feel hopeless and worthless. It also indicated that the decreased level of serotonin neurotransmitter in the brain of a depressed individual was found to be associated with increased suicidal behaviour.⁵⁰

Regarding anxiety, participants who had anxiety were 2.9 times higher likely to have suicidal ideation than participants who had no anxiety. This was similar with the study done in Canada,⁴³ Brazil,⁴¹ Korea³⁶ and Nigeria.⁴⁷ The possible reason for this may be fear of adapting to and anxious feeling about the illness and drug, fear of a seizure attack, increasing psychological stress and pressure related to epilepsy.

Another factor that was associated with suicidal ideation was poor social support. Respondents with poor social support were 2.35 times higher likely to have suicidal ideation as compared with strong social support. It was similar with other studies done in Havana city of Cuba,¹⁹ China⁴⁶ and Addis Ababa Ethiopia.²⁴ The WHO report revealed that weak social ties and low support from relatives have been significantly associated with suicidal ideation.⁵¹

With respect to a suicidal attempt, respondents who had depression were 4.87 times more likely to have a suicidal attempt than those who had no depression. This is consistent with study conducted in Canada,⁴³ Washington,³⁷ Poland,⁴⁴ Brazil,³⁸ Malaysia,⁴⁰ Korea,³⁶ Nigeria⁴⁷ and Addis Ababa Ethiopia.²⁴ The possible justification for this might be that depression will decrease the neurotransmitter serotonin, as studies have shown an association

between decreased level of serotonin and its metabolite and being suicidal.⁵⁰ On the other hand, depression can be a direct effect on the feeling of hopeless and worthless.

Those study respondents who were taking medication for mental illness in addition to antiepileptic medication were highly risk for suicidal attempt. This was similar to study conducted in Washington,³⁷ Croatia,⁴⁸ Korea³⁶ and Addis Ababa Ethiopia.²⁴ Having two chronic illnesses and pill burden to treat the illnesses took longer time to recover and make negative feeling, which could lead feeling hopeless and worthless and finally suicidal attempts.

Those study participants who had a family history of committed suicide were 2.8 times more likely to have a suicidal attempt as compared with those who had no family history of a committed suicide. The result is supported by the previous study done in Addis Ababa Ethiopia.²⁴ The possible reason might be due to biological perspective and might be due to non-biological factors like sharing similar family stress and environmental factors.

Regarding alcohol use, participants who had hazardous alcohol use were 2.1 times higher to a suicidal attempt as compared with those who had no hazardous alcohol use, this was supported by a study conducted in Croatia.⁴⁸ This might be due to participants who drink alcohol were exposed to increased impulsiveness, poor judgement and a weakening of normal restraints against dangerous behaviour. And they might also consider suicidal ideation in withdrawal state due to dysphonic feeling related with alcohol withdrawal.

Limitation of study

The use of retrospective items in the questionnaire may have incurred recall bias like duration of illness and duration of treatment. The cross-sectional nature of the study was its main limitation. In addition, the ever suicidal ideation and attempt were used to do the analysis as there were very few responses for the current suicidal ideation and attempt. This could be another limitation as it was difficult to determine the temporal relation between suicidal ideation and attempt and associated factors. It is difficult to address types of epilepsy since it was difficult to get specific diagnosis from the patient chart. Though there are evidences from previous study results that indicated the role of personality disorders in suicide, the current study did not assess personality disorders among patients with epilepsy.⁵²

CONCLUSION

This study showed that suicidal ideation and attempt were common among people with epilepsy. Being woman, living alone, single, divorced/widowed in marital status, family history of suicidal attempt, anxiety, depression, comorbid medical illness and poor social support were significantly associated with suicidal ideation. Family history of committing suicide, living alone, depression, taking medication for mental illness and hazardous

alcohol use were significantly associated with suicidal attempt. Therefore, it is better to give due emphasis and screen patients with epilepsy to suicidal ideation and ask history of suicide attempt including depression and anxiety as routine clinical evaluation. Providing intervention targeting risk factors to these groups of people is also vital.

Acknowledgements The authors acknowledge the University of Gondar for facilitating the study. We extend our gratitude to data collectors, supervisors and study participants for their time and effort in data collection and information provision.

Contributors KN designed the study, involved in the data collection, analysis and write up. HK and BT involved in design, data analysis and drafted the manuscript. AL participated in the analysis of the data and critically reviewed the manuscript. All authors read and approved the final manuscript.

Funding The authors have not declared a specific grant for this research from any funding agency in the public, commercial or not-for-profit sectors.

Competing interests None declared.

Patient and public involvement Patients and/or the public were not involved in the design, or conduct, or reporting, or dissemination plans of this research.

Patient consent for publication Not required.

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement Data are available upon reasonable request. All data relevant to the study are included in the article or uploaded as supplementary information. Data are available upon reasonable request to the corresponding author. Email: habtaishk@gmail.com
