Cost-effectiveness of household contact investigation for detection of tuberculosis in Pakistan

Hamidah Hussain, Amyn Malik, Junaid F Ahmed, Sara Siddiqui, Farhana Amanullah, Jacob Creswell, Thorkild Tylleskär, Bjarne Robberstad

ABSTRACT

Objectives Despite WHO guidelines recommending household contact investigation, and studies showing the impact of active screening, most tuberculosis (TB) programmes in resource-limited settings only carry out passive contact investigation. The cost of such strategies is often cited as barriers to their implementation. However, little data are available for the additional costs required to implement this strategy. We aimed to estimate the cost and cost-effectiveness of active contact investigation as compared with passive contact investigation in urban Pakistan.

Methods We estimated the cost-effectiveness of ‘enhanced’ (passive with follow-up) and ‘active’ (household visit) contact investigations compared with standard ‘passive’ contact investigation from providers and the programme’s perspective using a simple decision tree. Costs were collected in Pakistan from a TB clinic performing passive contact investigation and from studies of active contact tracing interventions conducted. The effectiveness was based on the number of patients with TB identified among household contacts screened.

Results The addition of enhanced contact investigation to the existing passive mode detected 3.8 times more cases of TB per index patient compared with passive contact investigation alone. The incremental cost was US$30 per index patient, which yielded an incremental cost of US$120 per incremental patient identified with TB. The active contact investigation was 1.5 times more effective than enhanced contact investigation with an incremental cost of US$238 per incremental patient with TB identified.

Conclusion Our results show that enhanced and active approaches to contact investigation effectively identify additional patients with TB among household contacts at a relatively modest cost. These strategies can be added to the passive contact investigation in a high burden setting to find the people with TB who are missed and meet the End TB strategy goals.

BACKGROUND

Tuberculosis (TB) remains a leading cause of morbidity and mortality, especially in low-income and middle-income countries. According to the latest estimates, 10 million people fell ill with TB in 2019, though only 7.1 million were reported to national programmes. Eight countries account for two-thirds of the reported TB burden in the world: India (26%), Indonesia (8.5%), China (8.4%), the Philippines (6%), Pakistan (5.7%), Nigeria (4.4%), Bangladesh (3.6%) and South Africa (3.6%). Reasons for the gap between estimated and notified individuals with TB include limited access to healthcare, poor diagnosis capacity for people who do access care, as well as under-reporting of people diagnosed.

Undiagnosed people with TB continue to transmit TB to others. The risk of transmission is particularly high among members of households living with people with undiagnosed pulmonary TB. Studies have documented an infection rate of 30%–50% among household contacts of infectious adults, with the infection rate in children under 5 being as high as 72%. Of those infected with TB, 10%–20% develop the disease over their lifetimes, and this number is even higher for people who are immunocompromised, for example, when they are coinfected with HIV.

Household contact investigation is recommended as a means to address these challenges. In the light of the high infection rates, household contact investigation is a critical activity for TB programmes for two reasons. First, it allows early identification
of additional household members who have TB disease and require immediate treatment, stopping transmission. Second, it allows programmes to identify people who can benefit from the treatment of TB infection to prevent disease progression, importantly children and people living with HIV. A meta-analysis of contact investigation showed that 3.1% of contacts in low-resource settings and 1.4% of contacts in high-resource settings have TB disease, making this a potential high yield strategy to find people with TB. A large proportion of childhood TB can be identified through contact investigation, which is of particular value since global rates of detection among children are much lower than for adults.1

Household contact investigation can be carried out in many different ways along a continuum of passive and active approaches.17 In passive contact tracing, the index patient is asked to bring in their family members for screening to the facility, while in active contact tracing, healthcare workers visit the index patient’s home. Between the active and passive modes, lies the ‘enhanced’ form of contact tracing, in which health workers make reminder phone calls and follow-up with the family and encourages them to come to the facility for screening. Despite WHO guidelines recommending household contact investigation18 and studies documenting the outcomes of active approaches most TB programmes in resource-limited settings only carry out passive contact investigation and even then, implementation is limited.19 20 A cluster randomised controlled trial demonstrated that contact investigation plus passive case finding (PCF) was beneficial compared with PCF alone.22 The cost of active contact investigation, including additional efforts required by already stretched healthcare providers, has often been cited as a barrier to its implementation.23 However, little data are available for the additional cost of implementing active contact investigation, and especially so when implemented under routine programme conditions. A study from Malaysia reported the cost of active contact investigation to be US$6.60 per a single contact tracing visit with a yield of 0.5%.24 In Peru, adding active contact tracing to PCF incurred an incremental cost of US$48.8 to evaluate household contacts of an index TB patient, with an incremental cost-effectiveness ratio (ICER) of US$1811 per Disability Adjusted Life Years (DALY) averted.25 We were not able to identify studies reporting costs or cost-effectiveness for the enhanced mode of contact tracing.

The objective of this study was to estimate the cost and cost-effectiveness of the enhanced and active contact tracing interventions in a high-burden programmatic setting, compared with the existing passive approach.

**METHODS**

**Setting**
The costing study was a subset of a larger study where an active case finding intervention was implemented for children with TB. The study was conducted at four TB treatment and reporting centres in Kotri, a rural town in Sindh, Pakistan. All children presenting to these facilities were verbally screened for symptoms of TB and those considered to be at high risk of having TB were further investigated. Children diagnosed with TB were started on treatment, and we conducted contact investigation for their household contacts.26 The household contact investigation reported here was carried out at one of the four centres (Institute of Chest Disease Hospital) from April 2015 to March 2016.

**Interventions**
For the study, the index patient was the first person identified with TB in the family, while household contacts were defined as people living in the same household as the index patient.

As part of the routine programme passive contact investigation is conducted where, index patients are counselled to bring their household contacts for evaluation. Contacts who respond are evaluated for TB symptoms and risk factors. A limitation of this approach is that household contacts screened were recorded only as a TB contact and not linked directly to the index TB patient in a specific household. There is no routine follow-up to see if the specific contacts attended the facility for screening or not.

As part of the intervention we instituted enhanced contact investigation as an additional step which included follow-up with the families for contact investigation. Adults and guardians of children under 15 years of age newly diagnosed with TB were asked about the presence of TB symptoms or household members on TB treatment in their families. They were counselled to bring their enumerated household contacts for evaluation, as in the passive approach. If the enumerated household contacts did not come to the facility for assessment after 1 week, a reminder phone call was made, followed by second phone call after another week. If the family still had not come 2 weeks after the second phone reminder, active contact investigation was implemented. Active contact investigation included health workers conducting a household visit to verbally screen the family at home and to counsel the family to go to the clinic for further evaluation (figure 1).

At the clinic, enumerated household contacts were screened by existing TB doctors in the passive system or by trained health workers for enhanced and active contact investigation. All contacts were verbally screened for symptoms of TB such as cough of more than 2 weeks, contact with someone other than the index patient who had TB, glandular swelling, fever lasting more than 2 weeks, night sweats and inappropriate weight loss. Individuals with suggestive symptoms or additional exposure were referred to the project’s medical officer for further evaluation. They then received a chest X-ray and were asked to provide a sputum sample for smear microscopy. A complete blood count and erythrocyte sedimentation rate was done for child contacts to aid in diagnosis as
indicated. Contacts diagnosed with TB were started on TB treatment in line with the National TB Programme (NTP) guidelines. Children under 5 years of age in whom TB disease was ruled out were offered isoniazid preventive therapy as per NTP guidelines. All clinical evaluations and investigations were provided without any charge to the contacts.

Data collection
For the passive approach, health facility staff recorded data using a paper-based system which were then abstracted for the study. For enhanced and active contact interventions project based trained community health workers and doctors administered questions to assess TB symptoms/risks and documented results of clinical evaluation and diagnostic tests using a custom-built smart phone-based data collection application with built-in decision support developed for the project.

Cost parameters
Costs for this systematic contact tracing activities were collected from the perspective of the operational programme and the health facility and included recurrent and capital cost items. As capital costs for the building were not available, we approximated rent and utilities of running a similar structure, and we used these in place of the capital costs.

We identified cost items and quantified resource use for all activities related to contact investigation. They included personnel, diagnostic test, supervision and monitoring by facility or project staff and communications. For the passive system, cost information was obtained from the health facility accounting system. We identified one physician and one health worker who were involved in the existing passive system at the TB clinic. We estimated their time spent on evaluation of household contacts through expert opinion and allocated salaries proportionate to this time as compared with other activities. Unit costs for TB diagnostic tests, chest X-rays and smear microscopy were as billed to the project by the health facility. Costs for diagnostic tests were estimated by multiplying their unit costs with the number of people tested. As communications, supervision and training costs for the existing passive programme were not available through the facility records, we assumed the same costs as incurred by the enhanced contact investigation intervention. At the TB clinic, data were collected on paper-based systems and the costs for registers and forms are reported with stationary.

For the additional costs of performing enhanced and active contact investigations, data were extracted from the project accounting system. One full-time health worker was recruited for enhanced intervention while the active contact investigation required three additional health workers. A fixed amount of travel costs for home visits was built into the salary for health workers. For all other personnel such as physician, field supervisor and programme coordinators, time spent on the contact investigation intervention was estimated using an activity-based costing methodology and costs were allocated according to the proportion of time spent on the intervention relative to other activities. Cost of diagnostic investigations per person screened (chest X-ray, smear microscopy and complete blood), communications (data and phone), training and stationery were as incurred. The cost for the development of electronic data capture was allocated based on the number of patients screened in each intervention, while the cost of phones and laptops used to capture data were allocated as per the personnel time that used them. We annuitised these capital costs over a period of 3 years using a 3% discount rate. Costs were collected in Pakistan rupees and converted to US dollars using the average exchange rate for the years 2015 and 2016 (US$1=PKR103.1).

Effectiveness of contact investigation
The effectiveness of the contact investigation procedure was evaluated based on the number of people with TB identified per household screened after verbal screening and diagnostic tests. Our study was divided into baseline and intervention periods. Historical data for passive contact investigation were used as the comparator. In the year preceding the intervention, the passive approach screened 762 contacts from a total of 231 index patient households to identify 21 people with TB during this

Figure 1 Household contacts evaluated and diagnosed for TB by passive, enhanced and active contact investigation interventions (CI). TB, tuberculosis.
baseline period (figure 1). During the intervention period, enhanced and active contact investigation were implemented, and contacts from 300 households were evaluated. Of these, 1,130 people from 144 families came to the health facility after phone reminders (enhanced) evaluated. Of these, 1224 people from 156 households that failed to respond to the enhanced strategy (active), we evaluated 1224 people and identified 53 additional people with TB disease (figure 1).

**Decision model and analysis**

A simple decision tree was created in TreeAge Pro 2020 (TreeAge Pro, Williamston, Massachusetts, USA) to estimate the cost-effectiveness of enhanced and active contact investigation compared with passive contact investigation. The decision tree includes the three alternatives for contact investigation; (1) Passive, (2) Passive +Enhanced and (3) Passive +Enhanced +Active (figure 2). The three intervention alternatives represent different levels of intensity of contact investigation and are considered to be mutually exclusive. The more intense alternatives are more expensive than the less intensive ones, but also represent new possibilities for identifying contacts with TB (table 1). The results are presented as absolute and incremental costs and patients with TB identified, and ICERS between the alternatives.

We conducted probabilistic sensitivity analyses using Monte Carlo simulations with 10,000 iterations to explore the effects of combined uncertainties in key parameters. Gamma distributions were used for cost parameters, and beta distributions for the probability of patients with TB per family screened. For sensitivity analyses, upper and lower values were defined for each parameter as mean values ±20%.

### RESULTS

In the enhanced and active contact tracing, 2,354 household contacts from 300 index patients were screened, of whom 49% were children less than 15 years of age, and 45% were female. The mean age for child contacts was 6.4 years (SD 3.7, IQR: 3–9), and 54% were males and the mean age for adult contacts was 33 years (SD 13.4, IQR: 21–41) and 53% were males. The enhanced contact investigation intervention was able to find 2.45 times (95% CI: 1.52 to 4.14) more people with TB than the passive programme when it was implemented. While the active intervention implemented 3 weeks following the index patient counselling identified 2.11 times (95% CI: 1.33 to 3.52) more people with TB compared with passive contact investigation.

Overall, the passive programme incurred US$10,659 over 1 year and it cost US$46 per household screened with TB. The enhanced contact investigation incurred an additional US$30 to screen a household with an overall addition of US$8938 to the yearly programme cost. Of the additional costs, human resources (42%) and electronic data collection (24%) were the most significant cost drivers. Active contact investigation incurred an additional US$42 per household screened for TB above the enhanced model, and the programme cost a further US$12,685 to the enhanced contact investigation of which human resources (57%) and electronic data capture (18%) were the largest components. (table 2)

The passive +enhanced contact investigation of one index patient was 3.8 times more effective than passive contact investigation alone, increasing absolute case detection rate from 0.09 to 0.34. The incremental cost was US$30 per index patient, which yielded an incremental cost of US$120 per incremental patient identified with TB. While the passive +enhanced-active contact investigation of one index patient was 1.5 times more effective than enhanced contact investigation with an incremental cost of US$238 per incremental patient with TB identified as compared with the baseline passive approach (table 3).

TB, tuberculosis.
for a range of willingness to pay for health when taking
the combined parameter uncertainty into account. The
enhanced strategy becomes optimal if the willingness to
pay exceeds US$120 per additional patient with TB that is
identified. If willingness to pay exceeds about US$238 per
TB case identified, the active contact investigation has
the highest probability of being cost-effective of the three
alternatives (figure 3).

One-way sensitivity analyses were conducted to explore
the impact of uncertainties in single model parame-
ters. These are represented in a tornado diagram in the
decreasing order of the parameters’ potential influence
on the ICER (figure 4). As the passive contact investigation
is standard we plotted the tornado diagram for enhanced
versus active contact investigation strategies. Cost and
effect parameters were varied over a predetermined range
(table 1). The ICER was most sensitive to the probability
of identifying a patient through active case finding, and
ranged between US$150 and US$600 per case detected
when probabilities were varied between 0.62 and 0.41,
respectively.

DISCUSSION
The enhanced contact investigation strategy, in combi-
nation with the passive system, was 3.8 times more
likely to identify patients with TB among household
contacts than the passive contact investigation alone.
The addition of household visits further improved case
detection and may be necessary if we are to achieve
the End TB strategy goals. Unsurprisingly, both the
enhanced and active strategies require more resources

ICER, incremental cost-effectiveness ratio; TB, tuberculosis.
Prevention, it played an essential role in decreasing TB incidence by 44% in the USA. A meta-analysis suggests that TB contact investigation should be considered to improve early TB case detection and decrease transmission in high-incidence areas as well. However, in low-income and middle-income countries, contact investigation has been viewed as expensive and, therefore, a low priority. Programmes do not undertake TB contact investigation as they have limited human resources. This project added health workers to support phone calls, counselling and home visits, which led to an increase in costs. However, these are necessary costs if we are to reach all people with TB. With contact investigation, people with TB are diagnosed early and initiated on treatment, which benefits the broader community by reducing continuing transmission. These benefits of future TB cases prevented over time are not captured by the current analytical model, and in this regard, our results can be considered to be conservative. If contact investigation interventions result in earlier detection of household contacts with active TB, this programme would reduce the spread of TB in the community even more effectively and be even more cost-effective.

Our study is subject to limitations. We initiated the enhanced intervention if the family did not come to the clinic for evaluation within 1 week of a patient with TB diagnosed and initiated on treatment. The passive system, if given more time than 1 week may potentially have had a larger yield. However, the historical data show that the number of people identified by the passive system during the implementation phase was similar to what we estimated in the baseline survey. Second, we only consider people with TB detected and did not consider outcomes of subsequent treatment in this analytical model. But in the larger project, in which this study was embedded, 98% of children diagnosed with TB were started on treatment and had over 94% treatment success rate. Third, out-of-pocket expenditures for patients was not considered. Costs such as transportation to the health facilities for evaluation, cost of diagnostic tests and loss of work time may be potential barriers for the majority of the TB affected families coming to the health facilities for evaluation. Arrangements for transportation of contacts to health facilities for diagnostic tests and transportation of sputum specimens for examination should be included in the national policy to increase the detection of patients with TB. Lastly, the household with child TB is likely to have transmission with in the household making contact investigation efficient and cost-effective in these contacts, but it may not be generalisable in household with an adult patients with TB. Future research may consider to conduct similar costing studies in the urban areas as the cost may be different than the rural setting in which our study was based and to integrate data on the overall economic burden to households that can be averted with an active TB contact investigation programme. In
addition, the study was conducted at only one centre, and other health facilities with different levels of pre-existing capacity and infrastructure may yield different cost estimates.

An important strength of the study is that it was performed alongside implementation in district TB clinics in a high-prevalence setting. Data were, therefore, collected prospectively in a programmatic setting. A robust monitoring and evaluation system was put in place, and the District TB Control Officers verified all notifications as would have been done in routine scale up.

CONCLUSION
Our results show that active approaches to contact investigation identify more people with TB among household contacts at a relatively modest cost addressing an identified global knowledge gap. These strategies can be added to passive contact investigation approaches in a high burden setting to find the missing patients with TB and meet the End TB strategy goals.
