ABSTRACT

Objectives Polycyclic aromatic hydrocarbons (PAHs) have been proven to be a risk factor for cardiovascular disease in coke oven workers, and increased plasma viscosity is a signal for higher risk of catching up cardiovascular disease. We want to explore whether the plasma viscosity is affected by the concentration of PAHs.

Design Our study is a cross-sectional dose-response study.

Setting Participants in this study came from a coke plant in Taiyuan, Shanxi.

Participants We used data of 693 coke oven workers in Taiyuan.

Primary and secondary outcome measures We assumed that plasma viscosity would increase as the concentration of PAHs metabolites in urine increases. We found that 2-hydroxyfluorene (OHFLU2) and plasma viscosity have a stable linear relationship in different statistical methods.

Results We found that plasma viscosity increased by 1.14 (mPa.s,30/s) for each ng/mL of 2-OHFLU urinary (correlation coefficient range: 0.54–1.74, $p < 0.05$).

Conclusions The results of this study could provide evidence for coke oven workers to prevent cardiovascular disease by checking whether plasma viscosity is elevated.

INTRODUCTION

Polycyclic aromatic hydrocarbons (PAHs) are air pollutants commonly present in the environment, mainly originating from the incomplete combustion of organic materials such as coal and petroleum products.^{1 2} PAHs can increase the risk of cardiovascular disease (CVD), as confirmed by many studies. A study by Xu *et al* found that in the USA, urinary metabolites of PAHs were associated with self-reported CVD.³ Another study in China suggested that some urinary monohydroxy PAH metabolites (OH-PAHs) have a relationship with arteriosclerotic CVD (ASCVD) risk.⁴ PAHs' association with arrhythmia has been confirmed in mammalian (including human) studies worldwide.^{5 6} PAHs' association with CVD has been extensively investigated, but

Strengths and limitations of this study

- This was a cross-sectional study and cannot prove causal relationship.
- We use the high-performance liquid chromatography with tandem mass spectrometry to measure 11 urinary monohydroxy polycyclic aromatic hydrocarbons in worker urine samples.
- The data source used in this study is 693 healthy coking plant workers.

its relationship to plasma viscosity is not yet known.

Plasma viscosity measurement is an important test item for haemorheology testing. High plasma viscosity is usually used as a signal of coronary heart disease and stroke. Compared with healthy subjects, plasma viscosity is higher in patients with ischaemic heart disease,⁷ and the higher the plasma viscosity is, the worse the severity of coronary heart disease tends to be.⁸ Plasma viscosity also may play an important part in atherosclerosis, thrombosis and ischaemia.⁹ There are many studies showing that higher plasma viscosity is associated with higher risk of CVD (ie, coronary heart disease and stroke) and mortality in the general population.^{10 11}

The range of normal plasma viscosity is narrow and independent of age and gender. It is not influenced by haematocrit (anaemia, polycythemia), red blood cell aggregation, haemoglobinopathias or time to analysis. Changes in plasma viscosity indicate decreased cardiovascular function. Plasma viscosity could be used as a biomarker for CVD. Serum biomarkers of CVD-like C reactive protein (CRP), fibrinogen and homocysteine have been well known and used as biomarkers to prevent CVD in human populations. But these serum biomarkers are not found to have an association with PAHs.¹² Our research focuses on whether there is a

dose–effect relationship between plasma viscosity and PAHs. The results of our study may provide a new marker for coke oven workers to prevent CVD.

METHOD

Study population

All subjects of this study were recruited in a coking plant located in Shanxi, China. These workers have worked for the coking plant for more than 1 year. People were excluded who had a history of encephalopathy, liver or kidney diseases or autoimmune diseases. A total of 776 coke oven workers were investigated in this study, but 76 workers were excluded from this study because of lacking urine samples. Nine workers were excluded due to a lack of data of plasma viscosity. A total of 691 participants were included in the final analysis. All study participants from the study prior provided informed consent. The informed consent form is found in online supplemental materials.

Our research group designed a questionnaire, and this questionnaire has been practiced before the final investigation, which is used to obtain the subjects' sociodemographic characteristics during these workers' working period, for example, the age, sex, nationality, occupational history, length of service, smoking and drinking habits, frequency of eating fried and coal-baked foods, histories of personal and family diseases, symptoms, medication used, etc. We defined smoking as currently smoking no less than one cigarette per day over the last 6 months, and drinking as currently drinking wine, beer or spirits no less than three times a week for the last 6 months. Of 691 exposed workers included in the study completed the questionnaire.

Biological sample collection and analysis

We used a urine container to collect urine sample from all participants who took part in the occupational examination. The urinary samples were immediately transported to the laboratory, and urinary gravity was measured initially. After that, the urinary samples were repackaged into 5 mL cryogenic vials, and then stored at -80°C until chemical analysis. Urine samples were measured for a suite of PAH metabolites: 2-hydroxynaphthalene (2-OH NAP), 1-OH NAP, 3-hydroxyfluorene (3-OH FLU), 2-OH FLU, 9-hydroxyphenanthrene (9-OH PHE), 2-OH PHE, 1-OH PHE, 1-hydroxypyrene (1-OH PYR), 3-hydroxychrysene (3-OH CHR), 6-OH CHR and 9-hydroxybenzo[a]pyrene (9-OH Bap), by high-performance liquid chromatography with tandem mass spectrometry (Shimadzu, Kyoto, Japan).¹³ High-performance liquid chromatography's separation conditions and mass spectrometry's detection programme were previously described in our study.¹⁴

Blood and biochemical indicators

Blood samples were collected from each participant according to the standard methods and used for routine blood examination (including white blood cell, red blood cell, absolute platelet count, absolute lymphocyte count,

absolute neutrophil count, monocyte count, mean corpuscular volume, mean corpuscular haemoglobin (MCH), MCH concentration) with a fully automated haematology analyser (XS-1000i, Sysmex Corporation, Kobe, Japan) and blood biochemical indicators (including alanine aminotransferase, aspartate aminotransferase, blood glucose, TCHO, TG, HDL, LDL) with a fully automated biochemical analyser (CS-400B, Dirui Industrial, Changchun, China). The measurement data of plasma viscosity in this study were provided by the cooperative hospital. The method used was lamina rotation (LBY-N6K automatic hemorheometer). This is the main method for whole blood viscosity detection. High, medium and low shear rate conditions are set for the determination, and the apparent viscosity of whole blood is measured at different shear rate.

Statistical analysis

We used SPSS V.22.0 (SPSS Chicago, Illinois) and SAS V.9.4 (SAS Institute, Cary, North Carolina) to analyse the data we collected. We used numbers and frequency (%) to represent categorical variables and mean $\pm$ SD for continuous variables. The detection rate of 3-OH CHR and 6-OH CHR in urine was less than 50%; therefore, we did not include the two urinary PAH metabolites in the final analysis. We used one-half the LOD to assign the concentration of PAH metabolites below the LOD for other PAH metabolites. We used the generalised linear models and restrict cubic spline models to explore the dose–response association between PAH metabolites and plasma viscosity after adjusting for potential confounders. Covariates were selected including age, sex, smoking, drinking, BMI, education, income, fruit, grease, TG, TC, HDL, LDL, OH-PAHs. A bilateral *p* value less than 0.05 was considered statistically significant.

Patient and public involvement statement

In this study, we collected data on coking plant workers. Coke plant workers who participated in the 2018 baseline survey may be selected as participants in this follow-up study. Workers who completely voluntarily fill in the informed consent form and provide blood and urine samples were involved in this study. Patients were not involved in the recruitment and conduct of the study. The information provided by the workers will be kept confidential under scientific numbering and strict management systems. The urine and blood samples provided by the workers will be destroyed after the study. We will disseminate the results to study participants by phone. This study is a cross-sectional survey and not a randomised controlled trials, there is no burden of the intervention.

RESULT

Characteristics of the coke oven workers

Table 1 shows the baseline characteristics of the 693 coke plant workers analysed in this study. Σ FLU is the sum of urinary 2-OH FLU concentration (ng/mL) and 3-OH

BMI, Body Mass Index; FLU, fluorine; NAP, naphthalene; PYR, pyrene.

FLU concentration (ng/mL). We put the population into a quartile based on Σ FLU concentrations in [table 1](#). It is shown that people exposed to high concentrations of Σ FLU are older men who are smoking and drinking. The blood lipid level of the high exposure group is also higher than the low exposure group. There was also a statistically significant difference in dietary habits and monthly income differences between these groups. Except for OH-NAP1 and OH-NAP2, other OH-PAHs of the high exposure group are higher. Plasma viscosity was also higher in the high exposure group, and the difference was statistically significant.

General linear model of OH-PAHs and plasma viscosity

We used two different models to test the relationship between concentration of OH-PAHs in urine and plasma viscosity and present the results in [table 2](#). In generalised linear model, plasma viscosity was positively associated with 2-OH FLU, 3-OH FLU and Σ FLU. (Adjustment for

age, gender, smoking, drinking, BMI, education, income, fruit, grease, TG, TC, HDL, LDL.)

Stratified analysis of OH-FLU2, OH-FLU3, Σ FLU and plasma viscosity

Then, the subjects were divided into four groups with the quartile of 2-OH FLU concentrations, 3-OH FLU concentrations and Σ FLU concentrations. After adjustment for age, gender, smoking, drinking, BMI, education, income, fruit, grease, TG, TC, HDL, LDL, and made the result into [figure 1](#). We found that concentration of 2-OH FLU and Σ FLU has a dose-response relationship with plasma viscosity at a high level and the trend test is statistically significant (p trend=0.02, 0.01). The adjusted β for higher plasma viscosity risk in the highest quartile was 0.70 (0.13–1.27) for 2-OH FLU, 0.97 (0.39–1.55) for Σ FLU, respectively.

Cubic limit spline graph of OH-PAHs and plasma viscosity

Then we made a cubic limit spline graph of OH-PAHs and plasma viscosity made it to [figure 2](#). The results from

FLU, concentrations (ng/mL) have a linear association with plasma viscosity. (P for overall association <0.05, and P for non-linear association >0.05.) The correlation between other metabolites in urine and plasma viscosity has no linear statistical significance.

Sensitivity analysis

We put other OH-PAHs into a linear model for sensitivity analysis (includes three OH-PAHs with low detection rates) and present the results in table 3. It was found that when the adjusted variables in the model did not include OH-FLU2 or OH-FLU3, the relationship between PAH metabolites of fluorene PAH metabolites of fluorene and plasma viscosity was still positively correlated and statistically significant. However, the relationship between OH-FLU3 and plasma viscosity was not statistically

significant after adding OH-FLU2 as an adjustment variable to the linear model ($p=0.12$). OH-FLU2 is the same ($p=0.19$).

DISCUSSION

We demonstrated for the first time that PAHs had an adverse effect on plasma viscosity. The results showed a significant association of 2-OH FLU level with high plasma viscosity. Plasma viscosity increased by 1.62 (mPa.s,30/s) for each ng/L of 2-OH FLU after adjusting for age, sex, smoking, drinking, BMI, education, income, fruit, grease, TG, TC, HDL and LDL. Plasma viscosity increased by 1.13 (mPa.s,30/s) for each ng/mL of 2-OH FLU. The effects of PAHs on CVD have been widely investigated, and the alterations in plasma viscosity could cause haemodynamic disturbances that may promote the formation of atherosclerosis.¹⁵ Our study demonstrates that plasma viscosity would change with the urinary levels of 2-OH FLU in healthy coke oven workers. The results of our study provide a new marker for coke oven workers who are exposed to PAHs to prevent CVD.

People are exposed to PAHs in daily life. The level of OH-PAHs in urine is widely used as a biomarker of PAH exposure.^{16 17} In our study, per cent detection of 2-OH NAP, 1-OH Nap, 3-OH FLU, 2-OH FLU, 9-OH PHE, 2-OH PHE, 1-OH PHE and 1-OH PYR was higher. However, the per cent detection of 3-OH CHR, 6-OH CHR and 9-OH Bap was minimal. This is likely because chrysene has a 4–5 ring structure, and it is more likely to be eliminated from the faeces, so the concentration of metabolites in urine is lower.^{13 18} In addition, 1.2%–13.4% of the exposure of PAHs in coke oven gas is pyrene, which mainly converts to 1-OH PYR after entering the human body, 1-OH PYR is the most commonly used OH-PAH biomarker.¹⁹ In our study, the GMSG ($\pm$ GSD) of urinary 1-OHPYR detected in coke oven workers of 0.2 ± 0.5 ng/mL is similar to the urban site's participants (MANHYIA) in Bortey-Sam *et al*'s study, which GMSG ($\pm$ GSD) of urinary 1-OHPYR is 0.208 ± 4.16 ng/mL.²⁰

The plasma viscosity of all coke oven workers is 5.57 (mPa.s,30/s) in our study, and the mean $\pm$ SD of plasma

viscosity is 4.60 ± 2.67 (mPa.s,30/s). According to the medical reference value (4.43–9.45), the plasma viscosity values of most workers were within the medical reference range. We found some papers working on the relationship between haemorheological changes and PAH concentration to find out if there are serum biomarkers of CVD, which is related to PAHs. Abou-Elwafa *et al* observed that the mean haemoglobin level and RBC count of healthy male service and office workers were significantly higher than those of the petrol station attendants.²¹ Another study focused on the relationship between PAH exposure and serum biomarkers of CVD,²² though these studies failed. However, past studies have found that people exposed to high levels of PAHs might have increased levels of white blood cells, CRP and fibrinogen.^{23 24} In our study, we can also see that there is an association between OH-PAH and plasma viscosity after reaching a certain dose (2-OH FLU >0.29 ng/mL CI 0.13 to 1.27). Therefore, this kind of association may be achieved with a certain dose, which makes sense for CVD prevention of coke oven workers.

Fluorene-related biological mechanisms of plasma viscosity are unclear. Studies about fluorene are rare, so we checked the studies working on the relationship between PAHs and CVD. After checking the studies on both humans and animals, we found a possible mechanism. One study has shown that coke oven workers exposed to PAHs may cause an acute systemic reaction increase and lead to a higher risk of CVD²⁵ and CRP, a serum biomarker of inflammation has been shown to be correlated with high concentrations of OH-PAHs in multiple studies,^{26 27} and CRP is one of the main factors affecting plasma viscosity. The change in plasma viscosity may be due to the inflammatory effect.

PAHs are associated with multiple CVD, like ASCVD, hypertension, etc. Studies have shown that many inflammatory factors are possible promoters of atherosclerotic plaques.²⁸ The number of inflammatory cells in atherosclerotic plaques significantly increased in the case of chronic PAH exposure in an animal experiment.²⁹ The relationship between PAHs and hypertension has been discovered in several studies. One study has shown that PAHs in housewives' hair is associated with hypertension,³⁰ and PAHs have been found to be associated with prehypertension in a study of children in Saudi Arabia.³¹ PAHs are associated with many chronic CVDs. Therefore, it may be more meaningful to find that plasma viscosity increase in the normal plasma viscosity range in healthy workers, indicating that plasma viscosity is related to chronic CVDs caused by PAHs. It is very sensitive in the early stage of the disease and is of higher value for prevention.

Our research has the following limitations. First, the population we studied was not a population already suffering from CVD or ASCVD, and it was not certain that changes in plasma viscosity were related to risk of CVD or ASCVD. Second, plasma fibrinogen concentration is a major factor affecting plasma viscosity. But our database does not have fibrinogen data. Therefore, we are not sure whether the change in plasma viscosity is mainly due to CVD. Third, the lack of a control group, a complete occupational history and

a complete clinical history. Finally, although we considered several important confounders in the analysis, our study does not include other confounding factors not measured or selected, such as genetic factors.

CONCLUSION

In conclusion, the results of this study could provide evidence for a relationship between PAH exposure (as measured by urinary levels of PAH metabolites) and biomarker of CVD (plasma viscosity).
