ABSTRACT

Objective To evaluate the benefits and risks of zinc formulations compared with controls for prevention or treatment of acute viral respiratory tract infections (RTIs) in adults.

Method Seventeen English and Chinese databases were searched in April/May 2020 for randomised controlled trials (RCTs), and from April/May 2020 to August 2020 for SARS-CoV-2 RCTs. Cochrane rapid review methods were applied. Quality appraisals used the Risk of Bias 2.0 and Grading of Recommendations, Assessment, Development and Evaluation (GRADE) approach.

Results Twenty-eight RCTs with 5446 participants were identified. None were specific to SARS-CoV-2. Compared with placebo, oral or intranasal zinc prevented 5 RTIs per 100 person-months (95% CI 1 to 8, numbers needed to treat (NNT)=20, moderate-certainty/quality). Sublingual zinc did not prevent clinical colds following human rhinovirus inoculations (relative risk, RR 0.96, 95% CI 0.77 to 1.21, moderate-certainty/quality). On average, symptoms resolved 2 days earlier with sublingual or intranasal zinc compared with placebo (95% CI 0.61 to 3.50, very low-certainty/quality) and 19 more adults per 100 were likely to remain symptomatic on day 7 without zinc (95% CI 2 to 38, NNT=5, low-certainty/quality). There were clinically significant reductions in day 3 symptom severity scores (mean difference, MD -1.20 points, 95% CI -0.66 to -1.74, low-certainty/quality), but not average daily symptom severity scores (standardised MD -0.15, 95% CI -0.43 to 0.13, low-certainty/quality). Non-serious adverse events (AEs) (eg, nausea, mouth/nasal irritation) were higher (RR 1.41, 95% CI 1.17 to 1.69, NNHarm=7, moderate-certainty/quality). Compared with active controls, there were no differences in illness duration or AEs (low-certainty/quality). No serious AEs were reported in the 25 RCTs that monitored them (low-certainty/quality).

Conclusions In adult populations unlikely to be zinc deficient, there was some evidence suggesting zinc might prevent RTIs symptoms and shorten duration. Non-serious AEs may limit tolerability for some. The comparative efficacy/effectiveness of different zinc formulations and doses were unclear. The GRADE-certainty/quality of the

STRENGTHS AND LIMITATIONS OF THIS STUDY

- ⇒ An extensive database search was conducted with no limits on language or date.
- ⇒ It is the first systematic review to analyse hazard ratios for symptomatic duration, day 3 mean symptom severity scores around the peak of acute respiratory illness and risks of adverse events.
- ⇒ The Risk of Bias 2.0 tool was used to appraise the risk of bias at the outcome level, and the Grading of Recommendations, Assessment, Development and Evaluation approach was used to appraise the quality/certainty of the evidence.
- ⇒ The study was limited by the rapid review methods, for example, where calibrated single reviewers were used.
- ⇒ Protocol changes and post hoc decisions as declared increased the risk of selective reporting bias.

evidence was limited by a high risk of bias, small sample sizes and/or heterogeneity. Further research, including SARS-CoV-2 clinical trials is warranted.

PROSPERO registration number CRD42020182044.

BACKGROUND

Acute viral respiratory tract infections (RTIs) are ubiquitous in the community. Clinical presentations range from milder cold and influenza-like illnesses to more serious conditions such as viral pneumonia and severe acute respiratory syndrome. Infection rates vary according to viral pathogen, location, season and the host's health status and age.¹ Although most infections are self-limiting, the high incidence leads to substantial healthcare costs and broader economic impacts from school and work absenteeism.²

Except for influenza and SARS-CoV-2 vaccinations, prophylactic and therapeutic options are limited. Clinical practice guidelines focus

on hand hygiene, reducing inappropriate antibiotic use and symptomatic relief with over-the-counter medications.^{3–5} Some guidelines recommend zinc.⁵ However, systematic reviews of zinc are limited by variations in administration route or formulation, are outdated, have been withdrawn or are low quality.^{6–11} The mechanisms for how zinc might work include broad spectrum antiviral properties in vitro against most of the common respiratory viruses, including coronaviruses.^{12–14} Zinc is important for immunity, inflammation, haemostasis, ACE 2 activity and also assists with tissue responses to hypoxia.^{13 15 16} Not surprisingly then, zinc has garnered attention during the global COVID-19 pandemic.^{13 15 17} Both high-income and low-income countries have seen increased zinc supplement use and sales.^{18 19} Some healthcare workers, clinicians and hospitals are already using zinc to prevent or treat SARS-CoV-2 infections.^{20–31}

In response to calls for rapid evidence appraisals to inform self-care and clinical practice during the COVID-19 pandemic,³² we developed a rapid systematic review protocol to evaluate zinc for the prevention and treatment of SARS-CoV-2 and other viral RTIs.^{33 34} At the time of this review, results from COVID-19 randomised controlled trials (RCTs) were all pending. Therefore, this rapid review updates previous systematic reviews of RCTs investigating any type of zinc intervention to prevent or treat viral RTIs in adult populations.

METHODS

Protocol

This rapid review conforms with Cochrane guidance^{35 36} and the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) (online supplemental file 1: PRISMA 2020 checklist).³⁷ Following feedback from our content experts, who at that stage were blinded to the search results, amendments to the registered protocol³³ were made pre data extraction and a revised protocol published.³⁴ Postprotocol input from consumer/patient advocate representatives who were blinded to the results, led to minor changes to the rating of the importance of outcomes. Due to very serious concerns with the indirectness of the available evidence and the importance of not overstating its relevance to the pandemic, the post hoc decision was made to remove COVID-19 from the title and not Grading of Recommendations, Assessment, Development and Evaluation (GRADE) the certainty of the evidence in the context of SARS-CoV-2 prevention or treatment. Further details about amendments to the protocol and post hoc decisions are reported below.

Search strategy

A research librarian (JB) experienced with systematic review led the search (online supplemental appendix 1). PubMed, Embase, Cochrane CENTRAL, Academic Search Complete, Allied and Complementary Medicine Database, Alt Health Watch, CINAHL Plus with Full Text, Health Source, PsycINFO, China Knowledge Resource

Integrated Database (CNKI), U.S. National Library of Medicine Register of Clinical Trials (ClinicalTrials.gov), International Standard Randomized Controlled Trial Number Register (ISRCTN), World Health Organization International Clinical Trials Registry Platform (WHO ICTRP), Global Coronavirus COVID-19 Clinical Trial Tracker and Chinese Clinical Trial Registry were searched from inception up to 8 May 2020, with no limit on language. This was supplemented by bibliography searches of included articles, and due to no eligible RCTs being identified in the first search additional post hoc COVID-19 focused searches were conducted up to 19 August 2020 that included the addition of covid19-trials.org, and medRxiv and bioRxiv preprint databases.

Eligibility criteria

Study design

Included were randomised and quasi-randomised controlled trials. Excluded were systematic reviews, non-randomised studies of interventions and studies without a concurrent control.

Population

Adults in any setting were included if they were at risk of contracting a viral RTI, had clinical illness with a laboratory confirmed viral RTI, or a non-specific respiratory tract illness that is predominantly caused by a viral infection, such as the common cold, non-seasonal rhinosinusitis, pharyngitis, laryngitis, influenza-like illness and healthy adults with acute bronchitis. Excluded were adults with bacterial infections and other respiratory illnesses when a viral infection was not confirmed.

Interventions and comparators

Included were interventions of any zinc conjugates, dose, duration and administration route. Excluded were co-interventions, including other nutraceuticals, herbs or pharmaceuticals unless both the intervention and control groups received the co-intervention. All types of controls and comparator groups were included.

Outcomes

A detailed list of critical (primary) and important (secondary) outcomes can be found in online supplemental appendix 2. Critical outcomes included incidence of RTIs, symptomatic survival, composite symptom severity scores, health-related quality of life (QoL) and serious and non-serious adverse events (AE). Important outcomes included the duration of symptoms and the number of different types of AEs.

Data collection and appraisal

In line with rapid review methods,³⁵ the first 30 title abstracts and 5 full papers were jointly screened for calibration. After which, single reviewers screened articles and a second reviewer screened the excluded articles (online supplemental appendix 2). Similarly, following calibration, single reviewers extracted data on the study design, funding, participants, interventions, comparators,

outcomes measures and effect size and direction into a piloted electronic spreadsheet that was verified by a second reviewer. For articles published in Chinese the second reviewer used Google translate to verify data extraction. Single reviewers also appraised the risk of bias (RoB) of study outcomes with the Cochrane RoB 2.0 tool³⁸ that was verified by a second reviewer (online supplemental appendix 3). However, discrepancies in calibration led to the post hoc decision to apply recommended systematic review methods where two reviewers independently appraise the RoB. Any disagreements or uncertainties were discussed with the other reviewers and resolved through consensus. Other review constraints included only appraising the RoB of outcomes that were meta-analysed or the primary outcome, not imputing missing data for secondary outcomes and not contacting the authors. Instead, additional information from previous systematic reviews was extracted.^{7 8 39} Data from graphical reports were extracted with WebPlotDigitizer V.4.2 (online supplemental appendix 4).⁴⁰

Statistical methods and evidence synthesis

RevMan V.5.4,⁴¹ R software,^{42 43} Microsoft Excel and GRADEpro GDT⁴⁴ were used. Studies reporting separate counts for different types of viral RTIs (eg, common cold, bronchitis, influenza-like illness) were combined to calculate the incidence of RTIs per person-months. Mean symptom severity scores were transformed to a modified Jackson common cold scale.^{45 46} Means were used as a proxy for median days duration of symptoms. Data extracted from symptomatic survival curves was imputed for the first 7 days using the direct method 10 in the 'HR calculations spreadsheet' published by Tierney *et al.*⁴⁷ Results and their 95% CIs are expressed as relative risks (RR) for dichotomous outcomes, incidence rate ratios (IRR) for person-time rates, mean difference (MD) or standardised MD (SMD) for continuous outcomes and hazard ratios (HR) for time-to-event outcomes. Absolute risks/rate differences and numbers needed to treat (NNT) or harm (NNH) are also reported. The Mantel-Haenszel method was used to calculate the pooled RR, generic inverse variance method was used for MD, SMD and IRR, and Q-E variance method was used for HR. Irrespective of statistical heterogeneity, due to considerable clinical and methodological diversity/heterogeneity, random effects models were used.

The Cochran Q test and I^2 statistic were used to measure heterogeneity.³⁶ Subgroup analyses followed published methods and was assessed with the χ^2 test.⁴⁸ A priori analyses compared age groups, RTI causes and severity, and zinc administration routes, salts and doses. Post hoc subgroup analyses compared days symptomatic prior to study enrolment and study definitions of symptomatic recovery. The three zinc dose subgroups (<50 mg daily, 50–200 mg daily, >200 mg daily of elemental zinc) were selected post hoc based on a no observed adverse effect level of 50 mg and a higher risk of more severe AEs, such as vomiting, with doses above 225 mg.⁴⁹

For SMD the minimally important difference (MID) was set at 0.5.⁵⁰ Except for an MID of 1-day reduction in the duration of the common cold,⁵¹ there was little consensus in the literature on the MID for the other measures of effect; therefore, these were set post hoc. For symptom severity on day 3 for mild RTIs, the MID for MD was set at 1 point on a standardised scale that was the half-way mark between two proposed MID (online supplemental appendix 4).^{51 52} Based on a 33% probability of remaining symptomatic on day 7 without any treatment,⁵³ the MID for HRs was set at 1.9 (ie, NNT=5).

The GRADE approach was used to grade the certainty (quality) of the effects estimates and for the Summary of Findings table (online supplemental appendix 5).⁵⁴ When data from at least 10 studies were pooled, funnel plots were created, visually inspected for publication bias and statistically analysed using Egger's regression for continuous outcomes and the Harbord score for dichotomous outcomes. However, due to ongoing methodological uncertainties, no statistical test was used for HRs.^{55 56}

Throughout the manuscript, zinc doses are reported as milligrams (mg) of elemental zinc. Further details about protocol and post hoc changes, RoB appraisal, statistical methods and GRADE-certainty assessments can be found in online supplemental appendices 3–5.

Patient and public involvement

The protocol was rapidly developed in response to a call from the WHO for rapid evidence reviews to inform self-care and clinical practice during the COVID-19 pandemic. The World Naturopathic Federation responded by setting review topics.³² The zinc protocol was published prior to direct patient advocate involvement. Experienced Australian patient advocates have since provided input on the outcome measures and the presentation of the results and discussion.

RESULTS

From the 1360 articles and registered trials screened (online supplemental appendix 1), 28 unique RCTs, reported in 25 articles, with 5446 participants met the inclusion criteria (figure 1).^{51 57–80} Three were published in Chinese language only.^{77–79} Online supplemental appendix 2 lists the 95 RCTs evaluating zinc in paediatric populations, articles published in English that were excluded at full-paper screen, and the characteristics of the seven registered RCTs evaluating zinc for SARS-CoV-2, all with pending results.

Study characteristics

Study participants were generally healthy with clinical symptoms consistent with a mild to moderate viral RTI (online supplemental appendix 3). None were infected with the primary pathogen of interest SARS-CoV-2. Only 1⁷⁴ of the 20 RCTs^{51 61–80} with community-acquired RTI reported the number of participants

Figure 1 Search results flow chart. CTRs, clinical trial registries; RTIs, respiratory tract infections.

with a proven viral infection. Six RCTs inoculated participants with a human rhinovirus strain (HRV 2, 13, 23 or 39).^{51 58–60} Most participants were younger than 65 years. Two RCTs also included older children and adolescents, notwithstanding, the mean age was around 37 years.^{63 66} Two RCTs included older adults from different ethnic backgrounds in the USA, many of whom had chronic disease comorbidities and were taking long-term medication.^{57 76} In another RCT, around one-third of participants had a history of asthma.⁶⁷ In the two RCTs that used oral zinc for prevention, zinc deficiency was excluded prior to enrolment.^{75 76}

Most studies were single centre, two-arm RCTs (n=26)^{57–78 80} and were conducted in the USA (n=19),^{51 57 59–66 68 70–73 75 76} followed by western Europe (n=5),^{58 67 69 80} China (n=3)^{77–79} and Australia (n=1).⁷⁴ The median sample size for prevention studies was 53 (range 32–1945) and for treatment studies 78 (range 12–279). At least half reported the RCT had sufficient statistical power for the study's primary outcome(s).

All but two RCTs reported at least one result that was used in a meta-analysis of a critical or important outcome.^{57 79} None of the RCTs reported mortality or other clinical outcomes relevant to severe or critical illness from acute viral RTIs or QoL outcomes. Four RCTs evaluated zinc for prevention,^{75–78} and 17 RCTs for treatment^{51 61–74 79 80} of symptoms consistent with a community-acquired viral RTI. Of the six RCTs that inoculated participants with HRV, four RCTs evaluated zinc for both prevention and treatment,^{58–60} one RCT for treatment only⁵¹ and one assessed the tolerability and AEs of a zinc lozenge.⁵⁸ Another RCT assessed AEs and safety of a zinc lozenge used by older adults.⁵⁷

The most common zinc formulations were lozenges followed by nasal sprays and gels containing either zinc acetate or gluconate salts. The daily dose of prophylactic oral zinc for community-acquired infections was 15 mg⁷⁵ or 45 mg⁷⁶ for 7 or 12 months, respectively. Sublingual lozenge doses to prevent or treat HRV inoculation and community-acquired infections ranged between 45 mg and 300 mg daily and were used

for up to 2 weeks.^{51 58–61 63–67 69 71–74} Doses for topical nasal zinc to prevent or treat community-acquired infections were substantially lower (0.9–2.6 mg/day).^{62 66 68 70 77–79} Twenty-five RCTs compared zinc to a placebo that was matched or partially matched. Two 4-arm RCTs used an active control lozenge containing quinine hydrochloride⁵¹ and a 2-arm RCT used a nasal spray containing naphazoline hydrochloride.⁷⁹

Certainty and quality of the evidence

Most of the prevention, duration, severity and AE outcomes had at least some concerns about their

overall RoB (online supplemental appendix 3 and figures 2–5). Consequently, except for the prevention of RTIs following HRV inoculation^{58–60} and risk of non-serious AEs with zinc compared to an active control,^{60 79} the GRADE certainty/quality of evidence was downgraded by one level for RoB (online supplemental appendix 5). This included the outcomes in which some studies had a high RoB, as the estimates of effects were robust following removal of these RCTs (online supplemental appendix 4). Serious AEs and symptom severity outcomes were downgraded another

RoB, risk of bias.

level for imprecision due to the small pooled-sample sizes (online supplemental appendix 5). There was considerable statistical heterogeneity for the zinc versus placebo duration outcomes (figure 4). The HR effect estimate was downgraded one level for inconsistency, as the heterogeneity was partially explained by clinical and methodological diversity in the subgroup and sensitivity analyses (online supplemental appendix 4) and the 95% CI mostly overlapped (figure 3). However, the mean days duration was downgraded by two levels, due to conflicting evidence from clinically important positive and negative effects, minimal overlapping of the 95% CI (figure 3) and neither the subgroup nor sensitivity analyses substantially reduced the heterogeneity (online supplemental appendix 4). At least 11 RCTs were industry funded, with a further seven receiving partial industry support (online

supplemental appendix 3). Publication bias was not strongly suspected (online supplemental appendices 4, 5).

Findings from prevention studies

Community-acquired infections

When oral or topical nasal zinc was compared with placebo controls, there was moderate certainty/quality evidence of a 32% lower RR of developing mild to moderate symptoms consistent with a viral RTI (IRR 0.68, 95% CI 0.58 to 0.80) (figure 2).^{75–78} Five RTIs per 100 person-months of zinc use were prevented (95% CI 1 to 8, NNT=20). The largest reductions in RR were for moderately severe symptoms consistent with an influenza-like illness (eg, elevated temperature). There was an 87% lower risk of developing moderately severe symptoms (IRR 0.13, 95%

CI 0.04 to 0.38) compared with a 28% lower risk of developing milder symptoms (eg, common cold) (IRR 0.72, 95% CI 0.61 to 0.85) (moderate certainty/quality).^{76–78} However, due to more people contracting mild RTIs, the absolute risk reduction/risk difference was higher. Five mild RTIs were prevented per 100 person-months (95% CI 2 to 7, NNT=20) compared with one moderate RTI per 100 person-months (95% CI 1 to 2, NNT=100) (online supplemental appendix 4).^{76–78} Subgroup analysis found no significant differences according to age or zinc administration route or dose (online supplemental appendix 4).

Human rhinovirus inoculation

The effect of zinc lozenges compared with placebo for preventing RTIs caused by HRV inoculation was evaluated in two pre-exposure prevention (PrEP) RCTs with 53 participants,^{58 60} and two post-exposure prevention (PEP) RCTs with 54 participants.⁵⁹ Zinc had no effect on the risk of developing a clinical cold (RR 0.96, 95% CI 0.77 to 1.21, moderate certainty/quality) (figure 2). There were no significant differences between the effects of zinc compared with placebo for either the PrEP or PEP subgroup, or in the subgroup analysis comparing the two groups (figure 2). There were similar non-significant findings for the risks of developing a laboratory confirmed infection (online supplemental appendix 4).

Adverse events

No serious AEs were reported were reported in the four RCTs that used zinc for prevention (low certainty/quality).^{75–78} Anosmia (loss of sense of smell) was not reported by the 1447 participants who used a zinc nasal spray nor the 1354 participants who used a placebo spray for 1 month (low certainty/quality).^{77 78} Compared with placebo, no differences in copper plasma concentration were found in the two smaller RCTs that evaluated 15 mg of oral zinc for younger adults over 7 months⁷⁵ or 45 mg for older adults over 12 months⁷⁶ (low certainty/quality). No differences in the of risk non-serious AEs from zinc compared with placebo controls were found (IRR 1.63, 95% CI 0.81 to 3.31, low certainty/quality).^{75 77 78}

Findings from treatment studies

Symptom severity

Compared with placebo, a clinically important reduction of more than one point in the day 3 symptom severity scores was found for sublingual and topical nasal zinc (MD -1.21, 95% CI -1.74 to -0.66, low certainty/quality) (figure 3).^{60–63 65} In contrast, no differences in average daily symptom severity scores were found (SMD -0.15, 95% CI -0.43 to 0.13, low certainty/quality).^{59 60 64} Subgroup analyses found no significant differences according to zinc administration route or type of viral infection (online supplemental appendix 4).

Symptom duration

During the first week of illness, participants who used sublingual or topical nasal zinc were 1.8 times more likely

to recover before those who used placebo (HR 1.83, 95% CI 1.07 to 3.13, low certainty/quality) (figure 4).^{61–63 66–72} An estimated 19 more adults per 100 were likely to remain symptomatic at the end of the first week if they used placebo rather than zinc (95% CI 2 to 38, NNT=5). Compared with placebo, zinc also reduced the mean duration of symptoms by 2 days (MD -2.05, 95% CI -3.50 to -0.59, very low certainty/quality) (online supplemental appendix 4).^{61–65 68–74} Results from the subgroup analyses that compared zinc salts, administration routes and zinc lozenge doses were inconsistent (online supplemental appendix 4). There was low certainty/quality evidence that zinc lozenges were equivalent to an active control (HR 1.06, 95% CI 0.79 to 1.41; MD -0.14 days, -1.20 to 0.92) (figure 4).⁵¹

Adverse events

No serious AEs were reported in the 19 RCTs that reported AEs (low certainty/quality).^{51 59–73 79} However, the risk of any type of non-serious AE was higher from zinc use compared with placebo (RR 1.41, 95% CI 1.17 to 1.69) (figure 5), with 14 more adults per 100 experiencing a non-serious AE (95% CI 9 to 20, NNH=7, moderate certainty/quality).^{59 60 62 63 66–71 73} Specifically, zinc increased the risk of nausea or gastrointestinal discomfort (RR 1.46, 95% CI 1.03 to 2.06),^{59 61 63 65–68 71–74} mouth irritation or soreness from sublingual lozenges (RR 1.55, 95% CI 1.05 to 2.29),^{59 61 63 65 66 72 73} and taste aversion from sublingual lozenges (RR 2.11, 95% CI 1.47 to 3.04),^{59 61 63 65 66 69 71 72 74} but not nasal irritation or pain from topical nasal sprays or gels (RR 1.22, 95% CI 0.72 to 2.05) (online supplemental appendix 4).^{60 62 70} Zinc lozenges were more likely than nasal sprays and gels to cause any type of non-serious AE (p=0.02) (online supplemental appendix 4). There was no difference in the rates of non-serious AE from zinc lozenges compared with active controls (RR 1.12, 95% CI 0.76 to 1.65) (figure 5).^{51 79}

DISCUSSION

Principal findings

This rapid systematic review and meta-analysis advances the evidence on the effects of zinc for mild to moderate RTIs in adults without zinc deficiency.^{7–10 39 81 82} However, despite additional searches through to August 2020, none of the RCTs were for the primary population of interest that was SARS-CoV-2 infection as the results from the registered clinical trials were all pending.

New evidence about zinc prophylaxis found that compared with placebo, zinc reduced the risk of developing symptoms consistent with a community-acquired viral RTI. The prophylactic effects were greatest for reducing the RR of developing more severe symptoms, such as fever and influenza-like illnesses. However, only four studies were identified, and none used laboratory tests to confirm a viral infection.

When zinc was used to treat symptoms consistent with mild to moderate viral RTIs, new evidence found that

compared with placebo, there were clinically important reductions in day 3 symptom severity, but not average daily symptom severity scores. The difference in the severity results may reflect reporting bias and imprecision, as results could not be extracted for 13^{58 59 66–74 79} of the 20 RCTs^{58–74 79} that evaluated symptom severity, and there was only one overlapping RCT⁶⁰ in the two meta-analyses conducted. Like previous reviews,^{7–10 39 81} compared with placebo there were clinically important reductions in symptomatic duration from zinc use. However, there was also an increased risk of non-serious adverse effects that may reduce the tolerability or acceptability of some zinc formulations.

In contrast to these promising findings, following human rhinovirus inoculations, compared with placebo, sublingual zinc did not reduce the risk of developing an infection or symptoms of a clinical cold, nor were there any significant effects on symptom severity or duration of illness when zinc was compared with an active control. While the number of studies and sample sizes were small, it still raises the questions about the *in vitro* versus *in vivo* antiviral effects of zinc ions, at least against rhinoviruses, and comparative effectiveness.

Strengths and weakness of the review

Limitations to the certainty (quality) of the evidence included concerns about the RoB for most prevention, severity and duration outcomes, along with imprecision in the symptom severity lowering effects and inconsistencies in the treatment effect sizes for symptomatic duration. Further details about the impact of individual studies on GRADE certainty assessment of RoB, heterogeneity, imprecision and the overall quality of the evidence can be found in online supplemental appendix 5.

The findings build on previous reviews.^{7–10 39 81 82} Compared with two other systematic reviews conducted in the same period,^{10 82} substantially more studies were identified in this review. This in part was due to searching non-English language databases and affirms calls to carefully consider which methods to restrict when conducting rapid reviews of traditional and complementary medicine.⁸³ Other strengths included being the first systematic review of zinc for RTIs to synthesise hazard ratios for symptomatic duration, day 3 mean symptom severity scores around the peak of illness and risks of AEs. RoB appraisal at the outcome level rather than the study level helped optimise GRADE-certainty assessments that were both conducted following calibration exercises. Notwithstanding, there is always a degree of judgement that may vary between reviews. For instance, when appraising the available evidence for risk of serious AEs, we rated down one level for RoB and another for imprecision. However, it might also be reasonable to judge the RoB as not serious and the overall GRADE assessment as moderate, rather than low certainty/quality evidence. The assessments of publication bias were a potential limitation. While publication bias was not strongly suspected, visual inspection

of funnel plots are necessarily subjective⁵⁶ and a statistical test for hazard ratios was not performed.

Like other rapid reviews, single reviewers conducted many of the tasks that increases the risk of errors and inconsistencies. Nevertheless, we applied rigorous checks. For example, the use of a detailed data extraction form led to our reviewers being the first to notice that there were two 4-arm RCTs⁵¹ in which the control lozenge contained an active ingredient, quinine hydrochloride that has broad-spectrum antiviral effects.⁸⁴ Reclassifying them as an active control addressed unexplained inconsistencies identified by previous reviewers.³⁹ Sensitivity analysis confirmed that the inclusion of these two RCTs, both with non-significant findings, did not substantially change the effect estimates for symptom duration (online supplemental appendix 4). We also determined that two earlier reviews^{9 11} had incorrectly included the day 4 symptom severity scores from two RCTs^{61 65} in their meta-analysis of average daily symptom severity. When these are removed, we found the effect of zinc was no longer significant.

Finally, while all protocol changes were declared, this increases the risk of selective reporting bias. Initiating the rapid review in the early stages of the COVID-19 pandemic necessitated rapid protocol development and registration. To help mitigate bias we sought blinded advice from our content experts and consumer/patient advocates and post hoc decisions were conservative with the rationale reported. Notably, while the published amendments³⁴ to the protocol inclusion/exclusion criteria led to RCTs that inoculated participants with HRV also being included, the additional findings did not favour zinc. Post hoc decisions also ensured that the very serious indirectness of the available evidence was not overstated in the context of SARS-CoV-2 prevention or treatment.

Is zinc more than a dietary supplement?

The role of zinc in viral RTIs appears to extend beyond supplementing nutritional intake to prevent or treat zinc deficiency.⁸⁵ The two RCTs that used prophylactic oral zinc excluded zinc deficiency prior to enrolment.^{75 76} While none of the other RCTs excluded deficiency, the risk was low as participants were generally healthy and the three RCTs conducted in China all used a low dose intranasal zinc spray (1.15 mg daily)^{77–79} that is unlikely to have substantial systemic effects.⁸⁶ The rationale for topical intranasal and sublingual zinc is based on the *in vitro* effects of zinc ions that can inhibit viral replication, stabilise cell membranes and reduce mucosal inflammation.^{14 86} However, other mechanisms may also be at play, at least for sublingual and oral administration as activation of T lymphocytes, monocytes and granulocytes has been observed in healthy young adult males within 24–48 hours of taking 15 mg of oral zinc daily.⁸⁷

Implications for clinicians and consumers

Zinc is readily available for consumers to self-prescribe. The marginal benefits, strain specificity, drug resistance and potential risks of other over-the-counter and

prescription medications^{88–98} makes zinc a viable ‘natural’ alternative for the self-management of non-specific RTIs. It also provides clinicians with a management option for patients who are desperate for faster recovery times and might be seeking an unnecessary antibiotic prescription.

However, clinicians and consumers need to be aware that considerable uncertainty remains regarding the clinical efficacy of different zinc formulations, doses and administration routes,^{39 67 81 86} and the extent to which efficacy might be influenced by the ever changing epidemiology of the viruses that cause RTIs. The largest body of evidence comes from sublingual lozenges and zinc gluconate and acetate salts, suggesting these are suitable choices. Yet, this does not mean that other administration routes and zinc salts are less effective. The new evidence on the prophylactic effects of low dose nasal sprays^{77 78} adds weight to the otherwise inconclusive findings from the handful of RCTs evaluating zinc nasal sprays or gels for acute treatment.^{62 66 68 70 79} A minimum therapeutic dose for zinc is also yet to be determined. An earlier review suggested the minimum dose for sublingual lozenges is 75 mg.⁸ However, our analysis does not support this conclusion. Further, a daily oral dose of 15 mg has been shown to upregulate lymphocytes within days,^{87 99} so it is plausible that much lower doses might also be effective.

The minimum time frame in which zinc should be started is also unclear. Most of the RCTs included in this review commenced zinc within 24 hours from the onset of symptoms and some guidelines have claimed that zinc ‘only works if you start taking them within 24 hours’.⁵ Yet, in the post hoc subgroup analyses, the duration of illness was also reduced in the subset of RCTs in which participants commenced zinc up to 3 days from the onset of symptoms. Further, in a preliminary analysis for one of the included RCTs, the investigators briefly report that the significant reduction in the duration of symptoms remained when participants with symptoms of up to 10 days duration were included in the analysis.⁶³

Alongside potential benefits, consumers also seek detailed information about adverse effects and tolerability. Zinc was found to increase the risk of non-serious AEs. No serious AEs were reported, suggesting the risk is low. However, it cannot be ruled out as RCTs, especially those with small samples, are not well placed to identify rare events. If the rule of three is applied to determine maximum risk,¹⁰⁰ then the upper 95% CI for a serious AE from prophylactic zinc would be 1.7/1000 person-months and for therapeutic zinc, 2.9/1000 participants. Indeed, postmarketing surveillance has identified cases of long-lasting anosmia associated with a zinc gluconate nasal gel.^{101 102} Reassuringly, a loss of smell was not reported by any of the 1364 young adults who used nasal sprays for 1 month. Notwithstanding, anosmia is an early SARS-CoV-2 symptom, so any use of topical nasal zinc during the pandemic should be carefully considered and monitored.

Copper deficiency is another concern. Plasma copper levels and other laboratory parameters were stable following 15 mg and 45 mg for 7 months and 12 months,

respectively.^{75 76} However, contamination of the zinc intervention was found in one RCT,⁷⁵ both RCTs were small and may be underpowered to detect a difference, only a single marker of copper status was measured,¹⁰³ and intestinal absorption of zinc is influenced by a variety of factors including diet, medications, chronic diseases and increasing age.^{15 17}

Implications for research

Given the limited therapeutic options for preventing and treating viral RTIs, further research is indicated to better understand zinc’s mechanisms of action, the optimum administration routes, formulations and dose, the minimum time-frame in which zinc should be started following an acute infection and the duration of therapy.

Except for one RCT that evaluated the effects of zinc on cognitive function,^{58 80} the symptomatic and functional impact on the participants’ QoL was not assessed. These outcomes are important to patients. Questionnaires like the Wisconsin Upper Respiratory Symptom Survey-24 that assess both symptom severity and QoL are therefore recommended.¹⁰⁴

The review findings align with calls for more immunonutrition research, particularly in populations with a higher SARS-CoV-2 risk.^{17 105} Results from seven RCTs evaluating various zinc doses, salts and administration routes for the prevention or treatment of SARS-CoV-2 are all pending. These RCTs will continue to be tracked and the review periodically updated and reported until there is moderate certainty/quality in the evidence, or no results are pending. However, based on the limited information reported in the protocols, some of the choices for zinc interventions appear to be arbitrary. Future SARS-CoV-2 clinical trials should consider replicating the RCTs with positive results for other viral RTIs and consider focusing on high-risk groups. Trials also need to determine if zinc requires a carrier or an ionophore, such as hydroxychloroquine,²⁸ and compare the risks and benefits. According to our review findings and preliminary in vitro SARS-CoV research,¹² it is plausible that zinc may be effective when used on its own.

CONCLUSIONS

In adult populations in which zinc deficiency is unlikely, our review found when zinc was used for prophylaxis, there was a lower risk of contracting a clinical illness consistent with a community-acquired viral RTI, but not following direct HRV inoculation. When used for treatment, zinc was found to shorten the duration of symptoms and reduce day 3 symptomatic severity, but not overall daily symptom severity. While there was an increased risk of non-serious AEs that may limit tolerability for some, the risk of serious AEs was low. Limitations to the GRADE certainty/quality assessments of the available evidence included a high RoB and/or small sample sizes in primary studies, and considerable heterogeneity in the duration effect estimates. We were unable to answer

questions about the comparative efficacy, effectiveness and acceptability of different zinc formulations and doses, and their mechanisms of action. Prior to recommending zinc, patient preferences, financial and opportunity costs, and availability of different zinc interventions should be considered. Clarification of the efficacy and mechanism of zinc in viral respiratory infections, including SARS-CoV-2 infections, warrants further research.
