ABSTRACT

Objective We aim to explore and compare the effect of global travel restrictions and public health countermeasures in response to COVID-19 outbreak.

Design A data-driven spatio-temporal modelling to simulate the spread of COVID-19 worldwide for 150 days since 1 January 2020 under different scenarios.

Setting Worldwide.

Interventions Travel restrictions and public health countermeasures.

Main outcome The cumulative number of COVID-19 cases.

Results The cumulative number of COVID-19 cases could reach more than 420 million around the world without any countermeasures taken. Under timely and intensive global interventions, 99.97% of infections could be avoided comparing with non-interventions. The scenario of carrying out domestic travel restriction and public health countermeasures in China only could contribute to a significant decrease of the cumulative number of infected cases worldwide. Without global travel restriction in the study setting, 98.62% of COVID-19 cases could be avoided by public health countermeasures in China only compared with non-interventions at all.

Conclusions Public health countermeasures were generally more effective than travel restrictions in many countries, suggesting multinational collaborations in the public health communities in response to this novel global health challenge.

INTRODUCTION

Novel infectious diseases appear to be emerging faster now than ever before, possibly driven by the systematic manipulation of nature by humans, not only through a variety of factors, including population growth, cross-species interactions, climate change and international travel and trade, yet also through weakening of natural barriers to disease emergence and persistence. Globally, as at 18 October 2020, a total of 39 442 444 people have been confirmed COVID-19 cases, including 1 039 406 deaths, reported by the WHO.¹ WHO declared COVID-19 a

Strengths and limitations of this study

- Under timely and intensive global interventions in the study setting, 99.97% of infections could be avoided comparing with non-interventions.
- The scenario of carrying out domestic travel restriction and public health countermeasures in China only could contribute to a significant decrease of the cumulative number of infected cases worldwide.
- Public health countermeasures were generally more effective than travel restrictions in many countries, suggesting multinational collaborations in the public health communities in response to this novel global health challenge.
- The analysis was limited to the study time. Our hypothetical scenarios were based on counterfactual and backtrack the results to compare with the current situations.

Public Health Emergency of International Concern on 30 January 2020² and then a pandemic on 9 March and called on Member States to respond to the COVID-19 pandemic by implementing nationwide COVID-19 countermeasure strategies.

In the absence of effective drugs and vaccines, non-pharmaceutical interventions were effective in controlling the SARS-CoV-2 transmission in different populations.^{3 4} A series of social distancing countermeasures including school closures and restriction on mass gathering were implemented to minimise risk of spread between humans. Travel restrictions were enforced by several countries to uphold border security and shut down the transmission passage from any imported infected cases. The decline of COVID-19 cases in China showed the effectiveness of non-pharmaceutical public health interventions, with their implementation exceptionally stringent as compared with most other countries.⁵ However, over the past 8 months, the

number of cases reported has increased rapidly without showing signs of decay around the world. Selection and implementation of intervention strategies appeared to be different across countries and regions in their responses to the early sign of disease spread, which could explain in part the current COVID-19 pandemic.

In February and March, WHO did not recommend imposing travel or trade restrictions on countries experiencing COVID-19 outbreaks.⁶ The International Health Regulations (2005) formulated the global joint response to the disease in order to avoid unnecessary international traffic and trade restrictions.⁷ WHO commented that travel and trade restrictions would cause more harm than good.⁸ More than 130 countries have implemented different forms of travel restrictions, including suspensions of flights, halting visa-on-arrival programmes, discouraging travel to and from high-risk areas and closing borders for foreigners.⁹ Recently, a few reports explored the effectiveness of travel restrictions on COVID-19 in different countries.^{10 11} To some extent, travel restrictions avoided the importation of infected cases by breaking the chains of transmission between different locations; however, the containment effect on COVID-19 pandemic was unknown. Nonetheless, an Australian study showed the travel restrictions to and from China were somewhat effective on containing the COVID-19 spread.¹²

The purpose of this study was to compare the current situations with our assumed scenarios under different intervention strategies to explore the effectiveness of different interventions in containing the COVID-19 transmission. Findings may support local decision makers to select intervention strategies particularly in relation to travel restrictions to prevent, contain and manage COVID-19 spread in the nearer future.

METHODS

Data sources

Size of population by country were obtained from Worldometer.¹³ Air flights data were obtained from the OpenFlights databases,¹⁴ which contains information of 7698 airports and 67 663 domestic and international routes and other related data. International routes were aggregated to the country level. Although number of travellers would most accurately reflect the population mobility, this exact information was not available; hence, we used the aircraft seating capacity as the best available proxy measure for analysis relating to number of travellers.

Information on travel restrictions against China was obtained from the National Immigration Administration (<https://www.nia.gov.cn/>) and complemented with information from the council on foreign relations (<https://www.thinkglobalhealth.org/article/travel-restrictions-china-due-covid-19>). Other travel restriction information was obtained from the International Air Transport Association (IATA) updated on 1 April 2020 (www.iatatravelcentre.com/international-travel-document-news).

Epidemic simulation model

We employed the SimInf R package to implement the COVID-19 spatio-temporal modelling.^{15 16} The model comprised multiple nodes and each node, representing one country, contained the susceptible (S), exposed (E), infected (I) and removed (R) compartments. Transitions between these compartments were modelled as a continuous-time discrete state Markov chain. Individuals' movements across different countries, which were estimated by the aircraft seating capacity as the proxy for number of travellers, were processed with scheduled events, causing the change of the population in each country. We only considered the movement of individuals in one country to a destination country, irrespective of the birth or death. The scheduled movements were carried on when the simulation in continuous time reaches the predefined time. The individuals were randomly sampled from the compartments affected by the event. At time t , there were $a_{ij,t}$ susceptible individuals moved from node i to j , while $a_{ji,t}$ susceptible individuals moved from j to i . The number of exposed, infected and removed individuals travelled from country i to j were noted by $b_{ij,t}c_{ij,t}$ and $d_{ij,t}$, respectively. Transitions between compartments in one country and the movements between different countries were illustrated by figure 1. The number of individuals' movements across countries were estimated to represent different scenarios. We implemented a classic SEIR transmission model to simulate the spread of COVID-19. For simplicity, we presented the deterministic version of the transmission model in each country, described by the following set of differential equations:

$$\begin{aligned}\frac{dS}{dt} &= -\frac{\beta SI}{N} \\ \frac{dE}{dt} &= \frac{\beta SI}{N} - \sigma E \\ \frac{dI}{dt} &= \sigma E - \gamma I \\ \frac{dR}{dt} &= \gamma I\end{aligned}$$

where $1/\sigma$ is the latent period with value of 6.4 days, and $1/\gamma$ is the recovery period with value of days.^{17 18} In our model, we set the reproductive number, $R_0 = 2.35$, corresponding to the effective contact rate $\beta = 0.8103$.¹⁸

We assumed 10 initial infectious cases of COVID-19 identified from Wuhan City of China. The number of susceptible individuals were set to the size of population in each country, while the number of exposed and recovered were all set to zero. We ran the models for 150 days and used the cumulative number of infections to investigate the influence of travel restrictions and public health countermeasures including social distancing, isolation of cases, quarantine of close contacts, etc, during the global spread of COVID-19. The first day of the simulation was set on 1 January 2020.

Modelling scenarios

Seven scenarios were modelled to simulate the spread of COVID-19 around the world (table 1). The base-line scenario for comparison was set assuming neither travel restrictions nor public health countermeasures.

Figure 1 The flow chart of transitions between compartments and movements between countries.

Additional six scenarios were then modelled assuming different combination of travel restrictions and public health countermeasures.

We separated global travel restrictions into three situations, that is, none, travel restrictions against China or multinational travel restrictions. After WHO declared COVID-19 a Public Health Emergency of International Concern, many countries imposed travel restrictions against China, most of which were effective on 1 February, 2020. Since March 2020, COVID-19 has spread around almost everywhere in the world. Responsive to this

pandemic, country-wide travel bans were implemented strictly worldwide. We collected the information on multinational travel bans from IATA¹⁹ (updated on 1 April 2020), from which we assumed global travel restrictions were carried out on 20 March 2020.

We separated the public health countermeasures into three situations, that is, none, public health countermeasures implemented in China, or global public health countermeasures implemented worldwide. In the study, public health countermeasures represented a series of activities reducing effective contact rate between humans.

Table 1 Assumed scenarios to simulate the spread of COVID-19

Scenarios	Travel restrictions against China (from 1 February)	Global travel restrictions (from 20 March)	Public health countermeasures in China (from 25 January)	Global public health countermeasures (from 25 January)
1 (baseline)	No	No	No	No
2	Yes	No	No	No
3	No	No	Yes	No
4	Yes	No	Yes	No
5	Yes	Yes	No	No
6	Yes	Yes	Yes	No
7	Yes	Yes	Yes	Yes

Table 2 Results for the run with median of the total cumulative number of infections

Scenarios	Median of cumulative infections at 150 days	Avoided median number of cases*	Reducing the estimated median number of infections (%)
1 (baseline)	420 520 763	–	–
2	385 399 261	35 121 502	8.35
3	5 809 925	414 710 838	98.62
4	4 832 306	415 688 457	98.85
5	417 781 694	2 739 069	0.65
6	5 270 174	415 250 589	98.75
7	133 575	420 387 188	99.97
Actual reporting†	5 708 365	414 812 398	98.64

*Compared with infections in baseline 1.

†Number of confirmed cases were derived from WHO data reported on 29 May 2020 (150th day since 1 January 2020).

These activities included isolating confirmed cases, quarantining close contacts, suspending public transports, closing schools and entertainment venues and banning public gatherings.²⁰ These public health countermeasures have been put in place to stop transmission of COVID-19 since late January 2020, which demonstrated a reduced daily contact by most, during the COVID-19 social distancing period, with most human interactions restricted to be held within each household.²¹ We assumed the global public health countermeasures were implemented in a less strict way than those in China. Therefore, for public health countermeasures implemented in China, we set the effective contact rate in China reducing 85% after 24 January 2020, whereas for global public health countermeasures, we set the effective contact rate among other countries reducing 50% from 25 January 2020.

Patient and public involvement statement

Patients and the public were not involved in this study.

RESULTS

Table 2 presented the median estimates of the total cumulative number of infections worldwide for each scenario. The cumulative cases would have reached more than 420 million if no countermeasures had been taken. On 29 May, there were 5 708 365 cases reported by WHO. The numbers of cases under scenarios 2 and 5 were far more than the actual reporting data, respectively, whereas that under scenario 3 were similar to the actual reporting data. The absolute number of cases in scenario 7 were far lower than the actual reporting data.

Interventions implemented in China contributed to the significant decline in the cumulative number of infections worldwide according to the scenarios 3, 4 and 6 in comparison with no action taken at all. In scenario 3, 98.62% of COVID-19 cases could have been avoided compared with the no-action baseline scenario. Implementing travel restrictions against China alone (scenario 2) had little effect on the controlling of global spread

of COVID-19, as no substantial reduction in cases was observed. In scenario 5, implementing international travel restrictions could have only avoided 0.65% of number of infected cases in comparison with the no-action baseline scenario. **Figures 2–3** and online supplemental figures 1–5 showed the spatial distribution of the cumulative number of infected cases over 150 days in each scenario.

DISCUSSION

Our modelling results showed that COVID-19 transmission could be contained by timely and intensive travel restrictions and public health countermeasures with multinational joint efforts at the early stage of spread, and consequently the risk of becoming pandemic could perhaps be mitigated. Haug *et al*²² quantified the change of R_t (ie, the effective reproduction number of COVID-19, an indicator to measure the transmission of SARS-CoV-2, defined as the mean number of secondary cases generated by a primary case at time t in a population) in relation to different adoption time of non-pharmaceutical interventions and reported that the earlier adoptions were associated with more benefits. China's rapid responses to the COVID-19 spread also demonstrated a successful case in the real world.⁵ While the spread of the pandemic follows an exponential pattern during the initial growth phase, it is particularly important to uptake the effective intervention strategies as early as possible, especially when facing the COVID-19 resurgence spread.

Reduction in cumulative infections and local transmissions of COVID-19 was somewhat attributed towards the aggregated public health countermeasures, and to a much lesser extent, international travel restrictions, which was consistent with previous studies using a similar analytic approach. Chinazzi *et al*²³ reported impose travel restrictions on mainland China had a modest effect on the epidemic trajectory. Wells *et al*¹⁰ showed that the travel restrictions as well as airport screening enforced in China and other countries were insufficient to contain the COVID-19 spread around the world.¹⁰ Russell *et al*²⁴

Figure 2 Cumulative cases at days 150 in scenario 1.

found that in general stringent travel restrictions might have little impact on the epidemic dynamics. Given several factors including complex human behaviours that could determine the spread of the current pandemic, lessons learnt from China's experience could be informative to initiate multiple public health countermeasures such as the grid-network of community-based health checkpoints,⁵ when facing a COVID-19 resurgence spread at present. Our study findings emphasised again the importance of carrying out collaborative public health countermeasures rather than simply placing travel restrictions.

Compared with previously reported number of COVID-19 cases,¹ those predicted under scenarios of either imposing travel restrictions against China or implementing global travel restrictions were greater than the real-world observations. That is, these strategies appeared to be ineffective or somewhat exaggerated. This finding indicated the intervention strategies implemented in China have played an important role on the control of COVID-19 spread in communities. On 23 January, authorities in Wuhan have taken a series of unprecedented COVID-19 countermeasures with millions of local residents strictly upholding these policies, including city lockdown, traffic suspension and quarantine.²⁵ Recent epidemiological studies have demonstrated that these

interventions have contributed to the interruption of the spread of SARS-CoV-2 transmission,^{25 26} which was consistent with our modelling analysis. The decrease of daily COVID-19 infections in China has provided another set of evidence of the field effectiveness of these public health countermeasures.⁵

Ideally, should most of the countries around the world have taken public health countermeasures including stockpiling medical resources, initiating emergency response procedures, screening high-risk population and promoting social distancing at the beginning of the epidemic outbreak, the global spread of COVID-19 could have been restricted to a much lesser extent around the world (scenario 7). However, as of 29 May, there were 5 708 365 cases reported by WHO, greater than the simulated finding under scenario of every member state taking precautionary countermeasures as early as January when city quarantine in China has been initiated. Compared with what we assumed that the public health countermeasures should have been carried out around the world from January 25, there was a 2-month window period during which the global health communities did not effectively responded. European countries began to implement a series of intervention strategies since mid-March 2020.³ The stay-at-home order has been issued in

Figure 3 Cumulative cases at days 150 in scenario 7.

the 42 states of USA in late March and early April.²⁷ Facing a possible reemergence of COVID-19 later this year, any countermeasures that have been proved effective in the field should have been implemented timely and strictly around the world.

The global travel restriction played a relatively modest preventive role on controlling the SARS-CoV-2 transmission in our analysis, which was consistent with previous studies.^{10 28} While any global travel bans could slow the rate of importing cases, but they cannot stop the spread of COVID-19 around the world.¹⁰ A systematic review of 23 studies has showed the travel restrictions were effective in delaying the epidemic trajectory but ineffective in stopping it.²⁹ Other concerns about the global travel restriction strategy include its consequences of global economic issues as well as social dissatisfaction in relation to human rights and discrimination.³⁰ Furthermore, one trade-off of the global travel restrictions would be related to a possible delay of appropriate responses in low-income countries because a large amount of medical resources via air transportation from developed countries could have been blocked down.⁹ While the variation in effectiveness of partial or entire travel ban was under investigation,^{12 28} our findings suggest travel restriction a somewhat robust strategy during the outbreak. Additional efforts may

invest on screening and quarantining travellers from high-risk regions at the transportation interchange and remain social distancing strategies in the communities.

Our study has some limitations. First, our analysis was limited to the study time at the early stage of COVID-19 spread. Our hypothetical scenarios were based on counterfactual and backtrack the results to compare with the current situations. Second, the finding of substantial variation in the geographic spread across countries reflected heterogeneous contact rates in different countries. Although the summary statistics around the world demonstrated a global benefit by means of public health interventions, each member state is encouraged to select appropriate countermeasures in its own setting to minimise the risk of COVID-19 resurgence spread becoming endemic. Third, we assumed aggregated strategies that could vary across different settings, and therefore, result should be interpreted with caution. Nonetheless, the rapid spread of this novel infectious diseases demonstrated adverse impact on the entire world with harms to the global health, economy and social governance. The COVID-19 pandemic has posed a major threat to our society, and no country could be immune to such complex issues and stay out of the multinational collaborations. In the face of this global challenge, the principle

of one health and one world should be encouraged by all nations to achieve global governance in public health.

CONCLUSION

Number of COVID-19 infected cases around the world could have been largely prevented by public health countermeasures in each country and, to a lesser extent, by the global travel restriction. Rapid response to this novel public health challenge requires multinational collaborations to carry out timely and intensive intervention strategies.
