ABSTRACT

Objectives Management of cardiovascular disease (CVD) is an urgent challenge in low-income and middle-income countries, and interventions may require appraisal of patients' social networks to guide implementation. The purpose of this study is to determine whether egocentric social network characteristics (SNCs) of patients with chronic disease in western Kenya are associated with overall CVD risk and individual CVD risk factors.

Design Cross-sectional analysis of enrollment data (2017–2018) from the Bridging Income Generation with Group Integrated Care trial. Non-overlapping trust-only, health advice-only and multiplex (trust and health advice) egocentric social networks were elicited for each participant, and SNCs representing social cohesion were calculated.

Setting 24 communities across four counties in western Kenya.

Participants Participants (n=2890) were ≥35 years old with diabetes (fasting glucose ≥7 mmol/L) or hypertension.

Primary and secondary outcomes We hypothesised that SNCs would be associated with CVD risk status (QRISK3 score). Secondary outcomes were individual CVD risk factors.

Results Among the 2890 participants, 2020 (70%) were women, and mean (SD) age was 60.7 (12.1) years. Forty-four per cent of participants had elevated QRISK3 score (≥10%). No relationship was observed between QRISK3 level and SNCs. In unadjusted comparisons, participants with any individuals in their trust network were more likely to report a good than a poor diet (41% vs 21%). SNCs for the trust and multiplex networks accounted for a substantial fraction of variation in measures of dietary quality and physical activity (statistically significant via likelihood ratio test, adjusted for false discovery rate).

Conclusion SNCs indicative of social cohesion appear to be associated with individual behavioural CVD risk factors, although not with overall CVD risk score. Understanding how SNCs of patients with chronic diseases relate to

STRENGTHS AND LIMITATIONS OF THIS STUDY

- ⇒ The social network characteristics (SNCs) of patients with chronic diseases in Africa are understudied but describing the relationship between SNCs and modifiable cardiovascular disease (CVD) risk factors could help inform interventions.
- ⇒ With a large sample of clinical and lifestyle survey data, we were able to investigate the relationships between SNCs and overall CVD risk (QRISK3 score) as well as with numerous individual CVD risk factors.
- ⇒ We used Efron's local false discovery rate method to adjust for multiple comparisons.
- ⇒ Although there is no prospectively validated cardiovascular risk assessment measure for this population at the current time, QRISK3 was chosen for this study because it has been used in other black African populations.
- ⇒ We present the results of a cross-sectional analysis and so we are not able to comment on causality.

modifiable CVD risk factors could help inform network-based interventions.

Trial registration number ClinicalTrials.gov identifier: NCT02501746; <https://clinicaltrials.gov/ct2/show/NCT02501746>.

INTRODUCTION

Management of cardiovascular disease (CVD) is an urgent challenge, especially in low and middle-income countries (LMICs), where more than 70%–80% of premature deaths from CVD occur.^{1 2} Appraisal of patients' social networks might help guide delivery of tailored, effective care for individuals with CVD and CVD risk factors. In fact, social network analysis has been applied to understand the spread and modification of

behaviours and risk factors for CVD, such as obesity, diet and tobacco use.^{3–7}

Social network characteristics (SNCs) may influence health outcomes by exposing individuals to resources, information and behaviours in ways that are associated with people who are important social ties (eg, spouses pressuring smokers into cessation) or exhibit some form of social capital (eg, the propensity of high school students to smoke increasing with the popularity of other smokers).^{5–10} Some network scholars theorise that social connections to individuals who exhibit positive health behaviours may reinforce personal identity and sense of belonging, encouraging the positive health behaviour.¹¹ This theory has been tested empirically when the adoption of a health behaviour was improved by creating networks in which individuals received reinforcement from more people in the network.¹² The type of relationship (including the sex of both individuals in a friendship) has also been observed to have implications for the diffusion of health characteristics such as obesity, possibly by altering individuals' norms.³ In health and other sociological contexts, studies have shown that in times of specific need, individuals may rely on members of their networks with whom they are less close but who have access to specific resources or information, reiterating the idea that health outcomes could be related to SNCs by mediating the diffusion of tangible and intangible resources.^{13–14} SNCs relationship with health outcomes is likely multifactorial, related to the number and type of connections an individual has as well as the context in which an individual needs or is exposed to resources, information and behaviours.

Egocentric networks are personal social networks constituted of the individuals ('alters') known by one person ('ego').¹⁵ Egocentric SNCs that are markers of social cohesion have been associated with health outcomes.¹⁶ Recent studies have shown that egocentric SNCs, such as network size, may be relevant to CVD through their beneficial relationship with physical activity.^{17–18} Smaller network sizes have also been associated with increased risk of stroke.¹⁹ Studies of social networks in LMICs have examined diverse health topics, including contraception use, infant mortality, mercury consumption and diarrheal disease.^{20–25} However, to our knowledge, there have been few studies of SNCs among patients with chronic diseases in Africa.²⁴

The purpose of this study, therefore, is to explore the relationship between CVD risk and egocentric SNCs of patients with diabetes and/or hypertension in Kenya. We hypothesised that SNCs indicative of stronger social cohesion (eg, larger network sizes, more social activities shared with alters, more frequent contact with alters) would be associated with lower overall CVD risk and modifiable CVD risk factors. Because it has been observed empirically that 'functionally specific' social networks (ie, networks composed of people with whom an individual discusses health or health problems) may be most relevant to health outcomes,^{13–26–27} we also hypothesised that

SNCs of health advice-only networks would be more strongly associated with health outcomes than SNCs of trust-only networks.

METHODS

Setting and participants

We analysed baseline data (n=2890) from participants enrolled in the Bridging Income Generation with Group Integrated Care (BIGPIC) study, a cluster-randomised trial designed to investigate whether group medical visits, in combination with or independent of a microfinance intervention, can reduce the risk of CVD among individuals with diabetes and/or hypertension in western Kenya. Inclusion criteria for the BIGPIC study were adults 35 years or older in the Academic Model Providing Access to Healthcare Partnership's chronic disease management programme with diabetes (fasting glucose ≥ 7 mmol/L), impaired fasting glucose (fasting glucose 5.6–6.9 mmol/L) or increased risk of developing diabetes (Leicester Risk Assessment score ≥ 7).^{28–29} All participants in both the BIGPIC study and in the analysis, we present here of BIGPIC participants' SNCs had either diabetes or hypertension (systolic blood pressure (SBP) ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg). Full details of the trial methods and procedures have been previously described.^{29–30}

Patient and public involvement

No patients or members of the public were involved in the design, analysis or reporting of this study.

Egocentric SNCs

To generate data on egocentric social networks, participants were asked to name up to five individuals with whom they discuss 'important matters' and up to five individuals with whom they discuss 'health matters' and to provide information about their relationships with those individuals.^{22–24–26–31–36} Asking study participants explicitly about 'health matters' to generate networks in which the members may be most relevant to health outcomes is an approach that has been deployed across several contexts, including to study the relationship between CVD risk factors and SNCs in a cohort in the Caribbean.^{18–26} The social network survey was pilot tested to ensure comprehension and is similar to social network instruments that have been used globally.^{18–24} We asked each participant to characterise the nature of each network connection and used this information to identify up to three non-overlapping egocentric networks depending on the matters she or he discusses with their respective alters: (1) trust-only network, exclusively for 'important matters,' (2) advice-only network, exclusively for 'health matters' and (3) multiplex network, for both 'important' and 'health matters.' For example, a participant who named three people total—one in response to both the 'important' and 'health matters' questions and two for 'health matters' only—has one multiplex,

Figure 1 Example of an egocentric network. This example participant responds to the social network survey saying she discusses ‘important matters’ with alter A and ‘health matters’ with alters A, B and C. Because the participant discusses *both* ‘important’ and ‘health matters’ with alter A, alter A is in the multiplex (trust and advice) network, leaving just alters B and C in the advice-only network and no alters in the trust-only network.

two advice-only, and zero trust-only alters (figure 1). Participants who did not name alters for any network are labelled ‘isolates’.^{8 15}

For each of the three networks and for each individual, we calculated five egocentric SNCs that represent social cohesion by representing the size of the network, strength of relationships and sex composition^{8 15}: (1) *degree*: the total number of alters in the network, (2) *mean duration of relationship*: the average duration of the ego’s relationship with alters, in years, (3) *mean frequency of contact*: how often, on average, the ego speaks with alters, on a five-item scale (options: never=1, at least every couple of months=2, at least monthly=3, at least weekly=4, at least daily=5), (4) *mean number of shared activities*: the average count of the number of organisations in which the ego participates with her or his alters (options: church, work, club, group medical visit, microfinance group, other (specify), none), (5) *proportion male*: the proportion of alters in the network who are men. In addition, *sex homophily* (the proportion of alters in the network who are the same sex as the ego) and *proportion kin* (the proportion of alters in the network who are immediate or extended family members (eg, cousins) of the ego) were calculated for each network for descriptive purposes.¹⁸

Clinical and socioeconomic characteristics

Clinical measurements included blood pressure, blood glucose, lipid panel and body mass index (BMI). Lipids and glucose were measured using the Cardiocheck PA and Freestyle Optimum point-of-care systems, respectively. Each participant had either a fasting or random lipid panel, depending on fasting status. Abnormal lipids were defined as: total cholesterol ≥ 5.17 mmol/L, high density

lipoprotein (HDL) ≤ 1.03 mmol/L, low density lipoprotein (LDL) ≥ 4.14 mmol/L, triglycerides ≥ 1.70 mmol/L.³⁷ A questionnaire at baseline elicited information on medical history and relevant health behaviours (eg, diet, physical activity, alcohol and tobacco use), tailored to local context.^{30 38} Participants were also asked about socio-economic characteristics and non-monetary indicators of wealth (eg, ownership of land, livestock and household construction and items). Summative clinical and wealth measures were calculated, including QRISK3 score, which measures 10-year risk of heart attack or stroke,³⁹ and the validated asset-based International Wealth Index (IWI).⁴⁰

The primary outcome of interest is QRISK3 score. Secondary outcomes are individual CVD risk factors⁴¹: diabetes status (self-reported diagnosis, or having fasting glucose ≥ 7 mmol/L or having random glucose ≥ 11.1 mmol/L), SBP, total cholesterol, LDL cholesterol, BMI, current tobacco use (of any form), diet (number of servings of fruit or vegetables per day), physical activity (moderate-equivalent minutes per week).

Statistical analysis

Table 1 provides an overall summary of the different statistical analyses performed. Demographic characteristics, primary and secondary outcomes, additional clinical measures and SNCs were summarised and stratified by sex to identify any sex-related differences in health, wealth and social networks within the population.^{42–45}

Bivariate summaries of SNCs in each network by categorised CVD risk factor were produced. For this, each risk factor was dichotomised using cut-off points that indicate

Table 1 Summary of statistical analyses performed

Analysis	Purpose	Models	Stratification or adjustment	Location
Descriptive statistics	Summarise study population's clinical and socioeconomic status, and demographic and social network characteristics	n/a	Stratified by sex	Tables 2 and 3, online supplemental table S2
Logistic regressions	Assess the relationship between each SNC and overall CVD risk as well as individual CVD risk factors	Models fit for each dichotomised CVD risk factor	Adjusted for facility, participant age, participant sex Models for total cholesterol and LDL additionally adjusted for fasting status	Table 4, online supplemental tables S3–S6; figure 2A–C
Multivariable regressions	Assess the relationship between each network type and CVD risk and risk factors	Saturated regressions with all SNCs for each network as independent variables	Adjusted for facility, participant age, participant sex, and self-reported participant health	Online supplemental table S7
Likelihood ratio tests	Assess whether the SNCs of particular network types accounted for variation in CVD risk and risk factors	Comparisons of linear and logistic regression models (for continuous and categorical variables, respectively) with vs without each network's SNCs For example, one comparison to assess the contribution of the health advice network is comparison of a model with advice and trust SNCs as independent variables vs a model with only trust SNCs to assess whether addition of advice network to trust network accounts for variation in CVD risk	Results adjusted for multiple comparisons using Efron's local false discovery rate method, set to 0.05	Figure 3

CVD, cardiovascular disease; LDL, low density lipoprotein; SNC, social network characteristic.

elevated risk status: QRISK3 $\geq 10\%$,^{39 46} SBP ≥ 180 mm Hg (as an additional cut-off of elevated cardiovascular risk, in line with the definition of hypertensive urgency, because most participants (approximately 93%) already met standard Kenyan criteria for hypertension),^{29 47} total cholesterol ≥ 5.17 mmol/L, LDL cholesterol ≥ 4.14 mmol/L,³⁷ BMI ≥ 25 , intake of fruits or vegetables per day < 5 servings and physical activity per week < 150 moderate-equivalent minutes.¹ Isolates across the network types (n=122) were excluded from these summaries of SNCs because SNCs cannot be calculated for participants with no alters. Similarly, participants with network-specific degree of zero were excluded from the summaries of respective subgroups (trust-only, n=2094; advice-only, n=1944; multiplex, n=611).

To characterise the effect of each SNC on each CVD risk outcome, we used multivariable regressions that included all five SNCs for each of the three networks (trust-only, advice-only and multiplex) as independent variables. Because social isolation may impact CVD risk,^{48 49} an additional categorical indicator variable for having no alters in a particular network was added, and covariates for other SNCs were set to zero for participants with no alters in that network. Durations of relationships, prior to taking their mean, and degree were $\log(x+1)$ transformed to account for skewness. All models were additionally adjusted for facility, participant age, sex and self-reported health (0–100) from a Visual Analog Scale.^{50–54} We examined the impact of network-specific SNCs on five continuous (SBP, and log-transformed QRISK, total cholesterol, LDL and BMI) and four categorical (diet, physical activity, tobacco use and diabetes status) outcomes in total, using linear and logistic regressions, respectively. The estimated

parameters and 95% CI show the independent effect, in terms of magnitude, directionality and variability, of each SNC on each outcome.

Finally, we use the same multivariable modelling framework to test the effect of each type of network on each CVD risk factor. Likelihood ratio tests of nested models were used to assess whether SNCs from a specific network were a significant source of variation for each of the primary and secondary outcomes. For each of the three networks, we captured the p values from four comparisons of models with versus without the network's SNCs. Online supplemental table S1 describes the nested models used in each of the 12 comparisons. For example, to quantify the effect of the health-advice network relative to trust and multiplex networks (see column 1 in online supplemental table S1), we make the following comparisons: (1) health-advice versus none, (2) health-advice plus trust versus trust only, (3) health-advice plus multiplex versus multiplex only and (4) health-advice plus trust plus multiplex versus trust plus multiplex. Each of these nested model comparisons isolates the effect of health-advice networks relative to the others. To adjust for multiple comparisons, we used Efron's local false discovery rate method, with the false discovery rate set to 0.05.⁵⁵

RESULTS

Participant characteristics

Demographic and socioeconomic characteristics

Participants had a mean age of 60.7 years (table 2). Nearly 90% of the participant population reported either no formal employment or monthly earnings of less than

Missing	3 (0)	2 (0)	1 (0)
KES, Kenyan Shillings.			

5000 Kenyan Shillings (KES) (approximately US\$50). A greater share of women than men reported no formal employment (67% vs 55%), and women who were employed earned lower wages than men. Among those with formal employment, nearly 30% reported earning less than 1000 KES (roughly US\$10) per month, again more predominant among women. Women were less wealthy than men (mean IWI 28.2 vs 32.2), and a smaller portion of women-owned livestock (61% vs 73%).

Cardiovascular risk factors

Forty-four per cent of women and men had a QRISK3 score greater than or equal to 10% (online supplemental table S2), and 14% of participants had QRISK3 score greater than or equal to 20% (16% of men vs 14% of women). Participants had a mean SBP of 157.5 mm Hg and 21% had diabetes. Women were more likely to be overweight or obese than men (50% vs 33%). Eighty-five per cent of participants reported eating fewer than five servings of fruit and vegetables per day, and 40% reported fewer than 150 moderate-equivalent minutes of exercise per week, similar by sex. Sixteen per cent of participants with a fasting test and 14% of participants with a random test had total cholesterol greater than or equal to 5.17 mmol/L. Abnormally low HDL (38% fasting test, 36% random test) and elevated triglycerides (45% fasting test, 35% random test) were more common patterns of dyslipidaemia than elevated LDL.

Egocentric SNCs

Overall, 122 participants—4% of women and 4% of men—were isolates; the other 96% of participants reported at least one alter in at least one of the mutually exclusive networks. Seventy-six per cent of participants had no trust-only alters and 70% had no advice-only alters, but only 22% of participants had no multiplex alters (table 3). Most participants had zero or one alter in any given network. Most participants spoke to alters daily, on average, but the majority shared no social activities with their alters. Multiplex networks showed a high degree of sex heterophily, with 67% of multiplex networks entirely comprising alters that were the opposite sex of the participants. Alters were also likely to be family members and known for more than 20 years.

SNCs' association with CVD risk

The distributions of SNCs, including network degree (figure 2A), within each network were similar among individuals with different QRISK3 levels (table 4). The summaries did not show large differences between No substantive differences were observed between SNCs and diabetes status or elevated SBP (online supplemental tables S3 and S4). Participants with any trust network alters were more likely to report a good than a poor diet (41% vs 21%) (figure 2B and online supplemental table S5). Similarly, participants with any trust network alters were more likely to report sufficient than insufficient levels of physical activity (29% vs 16%) (figure 2C and online supplemental table S6). No relationships were observed between SNCs and total cholesterol, LDL, BMI or tobacco use (results not shown).

Multivariable models of log-transformed QRISK3 did not show any association between SNCs and CVD risk (online supplemental table S7). Number of and mean frequency of contact with trust network alters had positive associations with good diet; number of advice and multiplex network alters had positive associations with sufficient physical activity. Number of advice network alters and mean number of activities shared with them had inverse relationships with SBP, while these same SNCs in the multiplex network had a positive association with SBP. Results for diabetes status, total cholesterol, LDL, BMI and current tobacco use are also shown in online supplemental table S7.

The results of the likelihood ratio tests indicated that the SNCs for the trust and multiplex networks explained a significant amount of variation in diet and physical activity, even after adjusting for multiple comparisons (figure 3 and online supplemental table S8). We did not find evidence that characteristics of any of the networks explained substantial variation in SBP, diabetes status, total cholesterol, LDL, current tobacco use or BMI.

DISCUSSION

This cross-sectional study examined the relationship of egocentric SNCs with overall CVD risk and individual CVD risk factors, in a population of individuals with diabetes or hypertension in western Kenya. The study population was materially poor and reported small egocentric social

*Isolates (122 participants) and 1 participant with missing data were excluded from the analysis. For each network, SNCs other than degree are only reported for participants who had at least one alter in that network.
SNC, social network characteristic.

networks. More than 40% of the study population had elevated CVD risk. SNCs were not associated with QRISK3 score in our analysis. However, SNCs representing social cohesion were associated with better diet and physical activity. This study expands research regarding egocentric social networks and CVD risk in an under-studied African context.

This cohort of Kenyan patients with chronic disease included a sizeable proportion with elevated CVD risk. Relatively few participants had elevated LDL cholesterol, but a large number having elevated triglycerides, a notable pattern of dyslipidaemia consistent with that previously reported in a cohort of patients at a Kenyan clinic with

type 2 diabetes.⁵⁶ Insufficient intake of fruits and vegetables, a leading preventable dietary risk factor for non-communicable disease-related morbidity and mortality worldwide,⁵⁷ was a highly prevalent CVD risk factor in our study population, consistent with findings of a nationally representative 2015 Kenyan survey.⁵⁸ Self-reported tobacco and alcohol use were uncommon, in contrast to a nationally representative survey in which 13% reported some form of tobacco use and 19% reported alcohol consumption.^{58 59}

The BIGPIC study population was rurally based and materially poor. Nearly all participants reported no formal employment or daily earnings less than US\$1.25/day,

Figure 2 Distribution of CVD risk status and behavioural CVD risk factors (diet and physical activity) by network and degree. Bars illustrate the distribution of CVD risk status and behavioural risk factors for trust, advice and multiplex networks by network degree (no alters, one alter or two or more alters). (A) CVD risk status (elevated CVD: QRISK₃ ≥ 10%), by network and degree. (B) Diet, by network and degree. (C) Physical activity, by network and degree. CVD, cardiovascular disease.

and the cohort's mean IWI also correlated with a Poverty Headcount Ratio of less than US\$1.25/day.⁴⁰ The severe financial poverty of our sample underscores the need to improve access to healthcare resources and design models of care delivery and healthcare financing that incorporate social determinants of health into chronic disease management.

Although we hypothesised that we would observe a relationship between egocentric SNCs and overall CVD risk as quantified by QRISK₃, no such association was evident. However, multivariable models suggested a possible inverse relationship between some advice-network SNCs and highly elevated SBP, adding to the conflicting evidence previously described in the literature. One methodologically similar study found no relationship between health-advice SNCs and hypertension in Caribbean population, after adjusting for demographic variables.¹⁸ Studies in US, English and Spanish populations have suggested protective relationships between egocentric SNCs and 10-year mortality from some forms

of CVD^{60–62} but found mixed evidence for relationships with hypertension outcomes.^{60 63 64}

We observed associations between egocentric SNCs and modifiable behavioural CVD risk factors, such as diet and physical activity. This pattern is consistent with findings from studies of egocentric social networks in other geographies that have suggested positive relationships between larger, more cohesive networks with more favourable physical activity and/or diet.^{17 18 65–67} One possible explanation for the apparent relationship between SNCs and physical activity is that individuals with larger egocentric networks may have more alters who are physically active, which could encourage the positive health behaviour.^{11 68} Social network scholars have also previously hypothesised that health outcomes may be related to SNCs through diffusion of information, resources and norms for behaviours and attitudes.⁸ Given that this study was cross-sectional and, therefore, we cannot comment on causality, we resist speculating on the mechanism of the relationships we observed. Identifying the mechanisms

Table 4 Egocentric social network characteristics, by QRISK3 and network

SNC, social network characteristic.

for any observed association between SNCs and modifiable behavioural CVD risk factors would require greater information about alters (eg, to control for homophily of health characteristics) as well as longitudinal data to observe changes to both networks and health over time, which may be possible in future publications leveraging data from the BIGPIC study.

We also initially hypothesised that the health-advice network SNCs would be more predictive of health outcomes than the more general trust network SNCs, based on previous studies of health-related egocentric social networks and theory of social networks’ functional specificity.^{13 18 26} Counter to our hypothesis, an association between health-advice network SNCs and these behavioural risk factors was not evident. Multivariable models suggested an association between advice and multiplex network SNCs and SBP. There was also an overall trend across bivariate and multivariable models suggesting an association between trust and multiplex network SNCs and diet and physical activity. It is possible that, at baseline, patients in the BIGPIC cohort rely more on core discussion networks for health-related information and resources than on the targeted mobilisation of health network resources that has been described in other

literature.^{13 26} The underlying reasons for this greater reliance on core discussion networks could be due to structural barriers (eg, poor access to established health resources such as clinics or geographic distance from socially weaker ties) or cultural norms (eg, preferring to discuss health problems only with family members).

We observed a relationship between SNCs of multiplex networks and risk factors such as diet, physical activity and SBP. Because many participants had multiplex networks comprising only one alter, often kin and opposite sex, we speculate that these multiplex-network alters were spouses, though we did not specifically confirm this in the social network survey. This type of strong relationship with alters, such as a spousal relationship, could be more influential over behavioural changes.^{8 69}

Study limitations

We acknowledge several limitations. First, because we present the results of a cross-sectional analysis, we are not able to comment on causality. Second, to preserve the brevity of the social network survey, questions eliciting real or perceived alter–alter relationships were not asked, so structural properties of egocentric networks could not be calculated. However, we have been able to evaluate

Figure 3 Results of likelihood ratio hypothesis tests for effect of social network characteristics on CVD risk factor outcomes, with multiple comparisons threshold indicated by vertical line. Owing to the compressed scale for p-values, we translated p-values to associated Z-scores to enable visible display of all models. Large negative Z-score deviations from zero correspond to smaller p-values for each comparison (online supplemental table S1). For example, a Z-score of 0 corresponds to a p-value of 0.5; a Z-score of -1.96 corresponds to $p=0.025$. The dashed vertical line at $Z = -5$ is the threshold for statistical significance after adjusting for multiple comparisons; points to the left of that line represent statistically significant comparisons. Colour indicates type of social network SNCs added (red: trust network, blue: advice network, green: multiplex network). The plot shows that trust networks have an impact on diet, and that multiplex networks have an impact on physical activity. BMI, body mass index; CVD, cardiovascular disease; LDL, low density lipoprotein; SNC, social network characteristic.

alter–alter relationships during follow-up assessments of the BIGPIC trial participants, which we intend to evaluate and report in future publications. Third, the social network survey did not elicit information about advice specific to the health outcome of interest (CVD risk or individual risk factors), which might have influenced the findings. Fourth, that participants understood that alters could be identified by the research team might have influenced results of the social network survey. Fifth, while we recognise that social networks may operate differently by gender in certain populations, gender-stratified analyses were not prespecified in the original analysis plan. We feel that this important issue can be pursued subsequently in future analyses. Sixth, because the health-related behaviours (diet and physical activity) were self-reported, there remains a potential for recall bias.⁷⁰ In addition, the point-of-care technology used to measure lipid levels may not be as accurate as serum lipid levels, especially in certain subpopulations; for example, LDL levels may have been underestimated.⁷¹ Finally, although there is no prospectively validated cardiovascular risk assessment measure for this population at the current time, QRISK3 was chosen for this study because it has been used in other black African populations.^{39 72 73} We recognise the shortcomings of this approach,^{74 75} but feel there is no currently available risk assessment tool that is superior. We anticipate that as increasing numbers of CVD cohort studies are completed in Africa in the future, more accurate and targeted risk calculators will become available, reducing this fundamental limitation.

Conclusions

The high and increasing burden of CVD in LMICs and the potential relationships between SNCs and CVD risk factors necessitate expanded research on social networks and CVD, especially in African populations.^{76–78} Our findings help to create a foundation for a more thorough understanding of SNCs of chronic disease patients in this context, which could help inform interventions for modifiable CVD risk factors.^{79 80} Ultimately, we hope that cardiovascular interventions can be implemented in ways that strengthen social networks, leveraging the relationship between SNCs and modifiable CVD risk factors to maximise health benefit, both in Kenya and worldwide.
