ABSTRACT

Objectives To assess the applicability of risk factors for severe COVID-19 defined in the general population for patients on haemodialysis.

Setting A retrospective cross-sectional study performed across thirty four haemodialysis units in midlands of the UK.

Participants All 274 patients on maintenance haemodialysis who tested positive for SARS-CoV-2 on PCR testing between March and August 2020, in participating haemodialysis centres.

Exposure The utility of obesity, diabetes status, ethnicity, Charlson Comorbidity Index (CCI) and socioeconomic deprivation scores were investigated as risk factors for severe COVID-19.

Main outcomes and measures Severe COVID-19, defined as requiring supplemental oxygen or respiratory support, or a C reactive protein of ≥75 mg/dL (RECOVERY trial definitions), and its association with obesity, diabetes status, ethnicity, CCI, and socioeconomic deprivation.

Results 63.5% (174/274 patients) developed severe disease. Socioeconomic deprivation associated with severity, being most pronounced between the most and least deprived quartiles (OR 2.81, 95% CI 1.22 to 6.47, p=0.015), after adjusting for age, sex and ethnicity. There was no association between obesity, diabetes status, ethnicity or CCI with COVID-19 severity. We found no evidence of temporal evolution of cases (p=0.209) or clustering that would impact our findings.

Conclusion The incidence of severe COVID-19 is high among patients on haemodialysis; this cohort should be considered high risk. There was strong evidence of an association between socioeconomic deprivation and COVID-19 severity. Other risk factors that apply to the general population may not apply to this cohort.

INTRODUCTION

COVID-19 continues to exert a significant strain on healthcare systems worldwide. It presents as a clinical spectrum, with severe disease often manifesting as respiratory compromise leading to significant morbidity and mortality. Patients on haemodialysis are particularly at risk. Traditional public health measures do not apply due to their obligation to travel to and from enclosed units for regular treatment, often on public or shared transport. While the long-term impacts of COVID-19 are still being characterised in this group, the risk of morbidity and mortality afforded by acute COVID-19 is clear.

The widespread dissemination of COVID-19 vaccinations has therefore been welcome among those receiving haemodialysis. Despite the successful roll out of vaccines globally, success is yet to become universal and vaccine hesitancy remains an issue even where they are readily available. Understanding which patients on haemodialysis are most at risk of severe disease is thus an issue of continued importance; it would facilitate patient counselling, public health measures in the event of further outbreaks, and would inform the development of disease modelling and risk scores which are becoming increasingly important clinical decision aids.
haemodialysis examined risk of mortality, mostly reporting age, frailty and comorbidity burden as important predictors.14-19 Severe disease represents a different but important clinical outcome, conferring significant mental and physical morbidity, and may have different risk factors that associate with it.12-25 Associations with this outcome have not been investigated in detail among patients receiving haemodialysis. Large studies that have investigated this among those receiving haemodialysis used hospitalisation as a proxy for disease severity — this may not always translate to severe disease. Especially early in the pandemic, admission was also prompted for logistical reasons, such being unable to dialyse a symptomatic patient with confirmed or suspected COVID-19.36

In this study, we chose to explore disease severity defined by the pragmatic and objective clinicopathological criteria set out by the RECOVERY trial (new oxygen requirement and/or a C reactive protein level ≥75 mg/L).27 We report the incidence of severe COVID-19 in patients on haemodialysis from 34 dialysis units, managed by 5 tertiary centres in the UK, and investigate the applicability of accepted risk factors for severe COVID-19 in the general population for patients on maintenance haemodialysis.

METHODS
Study design and participants
Data were collected retrospectively from 34 haemodialysis units across the UK, from 1 March 2020 to 1 August 2020. Participants included adults (≥18 years) with end-stage kidney disease (ESKD) of any aetiology receiving maintenance haemodialysis at the time of data collection, with the SARS-CoV-2 virus confirmed on PCR swab testing. The swabs were taken either in hospital, at dialysis units or from community testing, and for indications, including: development of symptoms suggestive of COVID-19; exposure to an individual with COVID-19; hospital admission screening (emergency and elective) or: routine clinical testing during inpatient hospital stay.

Following a recent directive from the UK Government Department of Health and Social Care on the Control of Patient Information in response to COVID-19,28 patient consent was not required. However, principles of the declaration of Helsinki, and the International Conference on Harmonisation Good Clinical Practice Guideline were followed. The lead centre for this work was University Hospitals of Leicester National Health Service (NHS) Trust (UHL) (registered project number 10802). Collection and sharing of anonymised patient data were approved with each participating renal network (online supplemental appendix 1). Subject data were deidentified within their local centres and data anonymity was maintained throughout.

Patient and public involvement
No formal patient and public involvement was under taken for this study.

Outcomes of interest
The primary outcome of interest was the development of severe COVID-19 infection, defined as new oxygen requirement and/or a C reactive protein level ≥75 mg/L.29 Admission to hospital during time of a positive SARS-CoV-2 PCR test, and 30-day mortality from date of a positive SARS-CoV-2 PCR test were also collected.

The primary exposures of interest were diabetes status (inclusive of all subtypes), body mass index (BMI), ethnicity, Charlson Comorbidity Index (CCI) and socioeconomic deprivation. Socioeconomic deprivation was identified through the UK government ‘English indices of deprivation 2019’ tool and was collected as deprivation ranks.30 Secondary exposures of interest included: blood pressure, haemoglobin, history of renal transplantation, immunosuppressant use, medical blockade of the renin–angiotensin–aldosterone system (RAAS) and vitamin D supplementation. Additional characteristics collected included: age, sex, date of progression to ESKD, dialysis vintage, dialysis access and location of dialysis.

Data collection
All data were collected from electronic hospital clinical records (laboratory results and observation charts). Medical records were requested to clarify any events that were uncertain from electronic documentation. Patient identifiers were removed from the data collection tool prior to transfer to UHL NHS Trust for analysis.

Statistical analysis
Data were locked prior to analysis using SPSS V.26 for Windows IBM Corp. as per the prespecified statistical analysis plan (online supplemental appendix 2). Categorical data are presented as frequencies with percentages. Ethnicity was classified as Caucasian (includes British, Irish, Northern Irish, English, Scottish, Welsh, Cornish, white European and any other white background) and non-Caucasian (all other ethnicity groups) for analysis. The CCI and socioeconomic deprivation rank were divided into quartiles. For socioeconomic deprivation rank, the first quartile represents the most deprived and the fourth quartile represents the least deprived. Distribution of continuous data were assessed visually using Shapiro-Wilk tests and Q-Q plots, and are presented as either mean with SD, or median with IQR, as appropriate. Univariate analyses comparing categorical risk factors by COVID-19 severity were completed using χ² tests. Continuous risk factors were compared using independent t-tests or Mann-Whitney tests dependent on data distribution. Unadjusted ORs were calculated for risk factors associated with severe COVID-19 infection. For social deprivation ranks, the ORs were calculated by comparing non-severe and severe COVID-19 infection for the first to third quartiles, to the fourth quartile. Logistic regression analysis with adjustments for age, sex and ethnicity (Caucasian and non-Caucasian) were planned for any primary exposure found to have statistically significant
relationship with COVID-19 severity. Data are rounded to three significant figures where appropriate. Patients with missing data were omitted from the analysis of that variable.

The influence of time on the incidence of severe and non-severe cases was explored, using the date of the first case of COVID-19 disease in our cohort as the reference. The median time in days from the first reported case was calculated for each new severe disease and non-severe disease case and were compared using a Mann-Whitney U test. Cumulative incidence of severe and non-severe cases over time was calculated as a percentage of total number of cases and explored.

Case cluster associations with disease severity were explored visually by plotting incident cases against time, for each dialysis unit, grouped by dialysis slots (Monday, Wednesday, Friday slots, or Tuesday, Thursday, Saturday slots), with overlapping shifts presented together, where these data were available.

RESULTS

Five dialysis networks contributed to data collection, gathered from thirty four haemodialysis units, as outlined in Table 1. The total prevalent haemodialysis population was 2899 patients; 274 had a positive SARS-CoV-2 viral PCR swab result during the 5-month data collection period, representing an overall incidence of infection of 9.45%. The 30-day mortality for the 274 patients with a positive SARS-CoV-2 viral PCR was 73 patients (26.6%).

Patients diagnosed with COVID-19 were categorised into groups of ‘non-severe’ (n=77, 28.1%) or ‘severe’ (n=174, 63.5%) COVID-19 infection. Severe cases thus represented 6% of the overall population at the time of data collection. Incomplete severity data were recorded for 23 patients who were excluded from further analysis. From the 251 patients included in the analysis, 67 (26.7%) died within 30 days of their positive SARS-CoV-2 swab result.

Baseline characteristics

Table 2 demonstrates the key demographic features. The outcome groups (non-severe COVID-19 and severe COVID-19) were well matched with regard to age, sex, length of time with ESKD, dialysis vintage, dialysis access and location of routine haemodialysis. There were significant differences between the outcome groups for admission to hospital ($X^2(1,N=251)=86.8, p<0.001$) and 30-day mortality ($X^2(1,N=244)=18.2, p<0.001$) (Table 2).

Primary exposures of interest

On univariate analysis, there was no evidence of an association between diabetes status, ethnicity (Caucasian vs non-Caucasian), BMI or CCI with severe COVID-19. These exposures were well matched between the two outcome groups (Table 3).

There was strong evidence of an association between socioeconomic deprivation and severe COVID-19. More patients living in the most deprived areas developed severe COVID-19 compared with those living in the least deprived areas. On unadjusted analysis by logistic regression, there was a greater risk of severe COVID-19 among the first quartile (OR 2.37, 95% CI 1.12 to 5.03, p=0.025), second quartile (OR 2.42, 95% CI 1.14 to 5.13, p=0.021) and third quartile (OR 2.57, 95% CI 1.18 to 5.57, p=0.017) of socioeconomic deprivation, compared with the fourth quartile (the least deprived). On adjusted analysis (Figure 1), the evidence for an association persisted: first quartile (OR 2.81, 95% CI 1.22 to 6.47, p=0.015), second quartile (OR 2.63, 95% CI 1.19 to 5.79, p=0.017) and the third quartile (OR 2.74, 95% CI 1.24 to 6.05, p=0.012).

Secondary exposures of interest

Most secondary exposures of interest were not significantly different between the outcome groups: previous renal transplantation, immunosuppressant therapy, RAAS blockade and systolic blood pressure (Table 3). There was strong evidence of an association between vitamin D supplementation for mineral bone disease treatment (OR 2.43, 95% CI 1.35 to 4.38, p=0.03) and severe COVID-19. There was also strong evidence of an association between haemoglobin level and severe COVID-19 ($t(249)=2.19, p=0.029$), with a mean haemoglobin level of 108 g/L in the non-severe group, and 103 g/L in the severe group (OR 0.981, 95% CI 0.964 to 0.998, p=0.031).

Time dependency and clustering

There was no difference in the timing of severe and non-severe case presentations to imply a time dependent effect of our findings (Figure 2). The median time to a

diagnostic PCR test for each new severe and non-severe case was 32 and 33 days, respectively, with respect to the first recorded positive test in our data set (Mann-Whitney U test p=0.209) (figure 2).

Clustering was investigated in 15 of the 34 units due to data availability (online supplemental figure 1). While episodes of clustering seemed possible, this appeared to have no pattern of influence on disease severity. Given the small number of cases in each unit and dialysis slot that could have clustered, it was not possible to perform any statistical analysis to investigate this further (online supplemental figure 1).

**DISCUSSION**

In this multicentre, retrospective, cross-sectional study, we investigated risk factors that associate with severe COVID-19 among haemodialysis patients. This study

produced three key findings. We found strong evidence that socioeconomic deprivation associates with severe COVID-19 (defined as new oxygen requirement and/or a C reactive protein level ≥75 mg/L) after adjusting for age, sex and ethnicity, while other risk factors reported in the general population may not apply to haemodialysis patients. This study also highlights the high incidence of severe COVID-19 and subsequent 30-day mortality among patients on haemodialysis.

Figure 1  Forest plot demonstrating the ORs on adjusted analysis when comparing the risk of developing severe COVID-19 between the most socially deprived (first to third deprivation ranks quartiles) and the least socially deprived areas (fourth deprivation rank quartiles).
The incidence of COVID-19 in our population matches national statistics for the period of data collection. Severe disease developed in 63.5% of those with COVID-19, considerably higher than in the general population, where it is estimated to be closer to 20%. This finding corroborates previously published data arising from smaller cohorts across the world, despite variable definitions for disease severity. This finding also adds credence to the notion that all haemodialysis patients should be managed as being at risk for severe disease. With COVID-19 vaccinations becoming readily available, these results should be used to encourage immunisations among this patient group, and prioritise vaccines for those receiving haemodialysis in areas where vaccine availability is yet to become universal. In the event of future COVID-19 outbreaks, further measures should include reinforcing social distancing, isolated dialysis when appropriate and rigorous infection prevention measures at all dialysis units.

The high incidence observed is likely to be multifactorial. The generalised immunosuppressed state of haemodialysis patients has been well documented and is further evidenced by their increased susceptibility to infections and muted responses to immunisations. Dialysis patients are also obliged to spend prolonged periods of time in enclosed, populated spaces to receive their treatment; this may increase their exposure to SARS-CoV-2 viral particles and subsequent viral load, particularly if other asymptomatic patients yet to be tested are dialysing out of isolation within the same unit, as may have occurred early in the pandemic. Indeed, this has been observed in the context of other communicable diseases which propagate through droplet transmission. As viral load correlates with disease severity, these factors together may predispose the entire haemodialysis cohort to severe COVID-19.

Despite the high rate of severe COVID-19 among haemodialysis patients, a proportion did not develop severe disease. We subsequently interrogated our data to determine if risk factors that associate with severe COVID-19 in the general population could be applicable to our cohort. Our key finding was strong evidence of an association between socioeconomic deprivation and COVID-19 severity among patients on haemodialysis. Socioeconomic deprivation has long been established as a predictor of poor health outcomes, and this has been demonstrated in the context of COVID-19.

We used the English Index of Multiple Deprivation (IMD) as a marker of social deprivation. The IMD is a weighted composite of seven domains (income, employment, education, health, crime, barriers to housing, and living environments) which assigns a rank to 32,844 areas in England, with a rank of one considered the most deprived on the index. We present strong evidence that the IMD associated with a greater risk of severe COVID-19, being most pronounced between the least and most deprived quartiles. This finding persisted after adjusting for age, sex and ethnicity (OR 2.81, 95% CI 1.22 to 6.47, p=0.015). The Scottish Renal Registry recently demonstrated patients living in more deprived areas were more...
susceptible to contracting COVID-19, and residence in a congregate setting conferred a 17-fold risk for developing COVID-19 in the USA, but to the best of our knowledge, this is the first study demonstrating a link between socioeconomic deprivation and COVID-19 severity in the haemodialysis population.

Determining the precise factors that account for the relationship between the IMD and COVID-19 severity among haemodialysis patients is beyond the scope of this study, however, there are a number of potential contributors that could warrant further investigation. Household overcrowding is incorporated into the IMD as a contributing factor of social deprivation. As with dialysis units, it is possible that this contributes to a greater exposure to viral load, should another member of the household be COVID-19 positive. Additionally, we were unable to collect data on patient smoking status, which may confound this association. Indeed, smoking is a possible risk factor for severe COVID-19, and smoking habits are four times as more likely in areas ranked as most deprived by the IMD. Other factors that may explain this association are likely to be less COVID-19 specific; dialysis patients living in areas considered to be deprived have poorer survival rates, and this may be reflective of the physiological stressors associated with socioeconomic deprivation. Exposure to noise pollution, crowding, threat of crime, poor nutrition and other life pressures, including job and housing insecurity, can contribute to a state of chronic stress. This exerts negative impacts on immunity and can promote proinflammatory states which predispose to cardiovascular frailty, and perhaps accounting for the poor outcomes noted in this population.

Obesity, ethnicity and diabetes status predict severity in the general population; however, we found no evidence of these factors associating with COVID-19 severity in haemodialysis patients. This finding is in keeping with results of smaller French (122 patients) and Chinese (154) studies. We also investigated the CCI, a weighted index that predicts ten-year survival in patients with multiple comorbidities as a risk factor for COVID-19 severity. The CCI has shown value in predicting severe COVID-19 in the general population, but again, we found no evidence of an association with severe COVID-19 among patients on haemodialysis. This finding contrasts with those reported by Stefan et al who found a positive correlation between CCI and COVID-19 severity in a cohort of 37 Romanian dialysis patients. However, the definition of severity used was different and a proportion of the patients in this study received treatments that included glucocorticoids, hydroxychloroquine, lopinavir-ritonavir and tocilizumab, which may have altered disease progression, confounding results. Other risk factors reported to be significant in the general population, including sex, cardiovascular disease and blood pressure were evenly matched in our severe and non-severe COVID-19 groups. These findings further corroborate the results of smaller previously published studies. It is possible that the risk conferred by haemodialysis for severe COVID-19 far outweighs that of the established risk factors defined for the general population, minimising their effect sizes in this select cohort of patients.

We also noted strong evidence of an association between prescribed vitamin D supplementation and severe COVID-19 (OR 2.43, 95% CI 1.35 to 4.38, p=0.03). Vitamin D prescription in the dialysis population is principally in its activated form, used for the management of chronic kidney disease-related mineral bone disease, and not for routine supplementation. Those supplemented with vitamin D are therefore at higher risk of hyperphosphataemia, secondary hyperparathyroidism and ultimately vascular calcification, all of which associate with poor outcomes. Rather than suggesting these data infer any causal relationship between vitamin D supplementation and development of a severe manifestation of COVID-19, it is more likely that this ‘relationship’ is driven by residual confounding of the indications for vitamin D supplementations and related comorbidity. A difference was also noted in the haemoglobin levels between those with severe disease and non-severe disease (103 g/L vs 108 g/L, p=0.029). Although both groups showed evidence of chronic kidney disease-related anaemia, they also appeared to be adequately treated and within the limits recommended by international guidelines. As with socioeconomic deprivation, establishing if these links are causal are beyond the scope of this study, but are hypothesis generating, nevertheless.

We opted to investigate severity over the commonly reported metrics of total incidence and mortality, as we found it to be more representative of the burden placed on healthcare resources by COVID-19, and an important clinical outcome with regards to the physical and mental morbidity. Mortality among those with COVID-19 on haemodialysis has been widely reported on, with age, frailty and co-morbidity burden featuring as strong predictors. However, mortality is commonly reported as a death occurring within 28 or 30 days of a positive PCR test and could therefore include mortalities not strictly attributable to COVID-19, particularly given the characteristics of those most at risk. Furthermore, risk factors for mortality may not be COVID-19 specific; this can be challenging to differentiate between and therefore act on from a public health perspective. Incidence is increasingly being accounted for by asymptomatic patients who place little strain on healthcare services beyond the need to dialyse in isolation. We found that COVID-19 severity as defined by the RECOVERY trial, associated with admission rates and mortality (p<0.001), and was therefore an adequate, relevant and generalisable marker for severity with regards to the objectives of this study. We opted to use the RECOVERY trial’s definition for COVID-19 severity as it provided a pragmatic and clinically relevant definition. Larger studies have investigated disease severity using hospital admission as a proxy. We opted to explore a different definition of severity; early in the pandemic admissions occurred...
to facilitate the logistics of isolated dialysis for COVID-19 patients who were otherwise well, and therefore an admission per se may not be truly reflective of disease severity.

The limitations of our study lie in our sampling methods, sample size and cross-sectional design. The issue of collider (sampling) bias has been highlighted in studies related to COVID-19.\textsuperscript{82} This arises from a risk of failing to appropriately identify COVID-19 cases. This may occur because: (1) certain symptomatic groups are systematically less likely to get tested for COVID-19 and (2) the prevalence of asymptomatic patients identifiable only through protocolised or opportunistic testing. The first issue could be considered mitigated in our study by virtue of our patients all being dialysis dependent. Every patient included would have presented to either a hospital or a dialysis unit for dialysis, where they would have been screened for COVID-19 symptoms as a matter of protocol. Thus unlike in the general population, all symptomatic patients would have been tested for COVID-19, reducing this risk of a sampling bias. There is a risk that the PCR tests performed returned a false negative. Again, the cohort of patients we report on would have been subject to repeat testing on each visit if symptoms persisted, reducing the risk of false negatives contributing to collider bias.\textsuperscript{83, 84}

Our study did exclude asymptomatic patients who would not have been tested for COVID-19 at all. This is a reflection of testing availability and protocols that were being followed early in the pandemic. While the exclusion of this patient group could influence our findings, we believe this impact to be minimal; the burden of asymptomatic disease among haemodialysis patients in Midlands of the UK, where most participating units were based, was likely to have been low. We note a study from Oxford that was performed over a similar time period as our study found a prevalence of 1.8\% of asymptomatic disease.\textsuperscript{81} A study from Canada, which had a case-population ratio similar to that of the UK over the same period reported even lower rates.\textsuperscript{85} We also note a study from London which quoted a prevalence of 12\% of asymptomatic patients, but are aware the case burden of COVID-19 early in the pandemic was much higher in the capital than it was in the Midlands.\textsuperscript{86, 87}

This work, therefore, included all haemodialysis patients for whom data was available, who tested positive for the SARS-CoV-2 virus on a PCR test during the first wave of the UK’s COVID-19 pandemic. Although this is one of the larger studies investigating severity among of COVID-19 among haemodialysis patients, the relatively small sample size available limited its ability to identify smaller effect sizes that may have been exerted by the investigated exposures. It also prevented us from providing further granularity with regards to both ethnicity and socioeconomic deprivation and their associations with severe COVID-19, prompting a restriction in our analysis to Caucasian versus non-Caucasian and quartiles of socioeconomic deprivation, respectively. Given this was a cross-sectional observational study, causality cannot be inferred, and indeed it is likely that social deprivation associates with other key determinants of COVID-19 severity that was beyond the scope of this study.

**CONCLUSION**

We confirmed a high incidence of severe COVID-19 among patients on haemodialysis and found that risk factors that apply to the general population may not be applicable in the same way for patients on haemodialysis. For patients on haemodialysis socioeconomic deprivation appears to be more closely associated with COVID-19 severity, but further work is needed to establish whether there is because of a causal link, or whether there are confounding factors that account for this finding.

Risk Factors for Severe COVID-19 Among In-Centre Haemodialysis Patients.

Statistical Analysis Plan

Study Title: Risk factors for severe COVID-19 among in-centre haemodialysis patients.

Short Title: Severe COVID in ICHD patients.

1. INTRODUCTION

1.1. STUDY BACKGROUND

Coronavirus disease 2019 (COVID-19) presents on a clinical spectrum, with severe disease requiring supplemental oxygenation, escalating to mechanical ventilation and even extra-corporeal membrane oxygenation (ECMO) in extreme cases. Factors influencing the severity of presentation has been rigorously interrogated in the general population, and include cardiovascular disease, diabetes mellitus, chronic lung disease, obesity, malignancy, immunosuppression and chronic kidney disease. The elucidation of these factors has directly informed public health advice, by defining at-risk patient groups who are advised to strictly social distance or shield, and is likely to guide rationing of the recently approved vaccinations.

Although those who require in-centre haemodialysis (ICHD) fall into the high risk category, not all develop severe disease. Understanding risk factors for severity of COVID19 among ICHD patients is of the utmost priority; traditional public health measures cannot apply to this group due to their obligation to travel to and from their units, and the need to interact with health care professionals at least three times a week. In this study, we report the incidence of COVID19 among HD patients in the midlands, a strongly multi-ethnic region in the United Kingdom, and explore risk factors for severity of infection, defining a cohort for whom added protective measures may need to be considered in the context of global easing of ‘lockdowns’, and perhaps who should be prioritised for vaccinations when they become available.

1.2. STUDY OBJECTIVES

This study aims to provide insights into unresolved questions regarding risk factors that may predispose to severe COVID19 among in-centre haemodialysis (ICHD) patients.

Hypothesis:

1. Obesity, diabetes, ethnicity are risk factors for severe COVID19 among ICHD patients

2. The Charlson Co-morbidity Score and Socioeconomic Deprivation are risk factors for severe COVID19 among ICHD patients

1.3. STUDY DESIGN

The study design is a multi-centre, retrospective cross-sectional observational study.
1.4. SAMPLE SIZE

Estimated sample size based on UK renal registry data is 350. This is the total number of patients with COVID19 in dialysis units based in the midlands between February 2020 to August 2020, and is therefore all the data available to us at present. Based on our pilot data of 69 patients, this sample should be adequate enough to detect the effect of BMI, Diabetes and Socioeconomic deprivation (as measured by the index of multiple deprivation (IMD)), however it may not be adequate enough to detect the effect of ethnicity or the Charlson Co-morbidity index. Sample size calculations were performed assuming an alpha of 0.5 and a power of 80% (https://clincalc.com/stats/samplesize.aspx):

- Severe COVID in BMI >/=25 = 70%
- Severe COVID in BMI <25 = 51%
- Alpha 0.5, Power 80%
- Total n = 206 (103 in each group)

- Severe COVID in Diabetes = 76%
- Severe COVID in non-diabetics = 45%
- Alpha 0.5, Power 80%
- Total n = 76 (38 in each group)

- Severe COVID in White British = 58%
- Severe COVID in other ethnicities = 53%
- Alpha 0.5, Power 80%
- Total n = 3100 (1550 in each group)

- Severe COVID in lowest IMD deciles = 53%
- Severe COVID in highest IMD deciles = 23%
- Alpha 0.5, Power 80%
- Total n = 80 (40 in each group)

- Severe COVID in Charlson Index >/= 5 = 55%
- Severe COVID in Charlson Index < 5 = 50%
- Alpha 0.5, Power 80%
- Total n = 3130 (1565 in each group)

1.5. STUDY POPULATIONS

All ICHD patients who tested positive for COVID19, on a hospital based real time reverse transcription quantitative polymerase chain reaction tests, were included in this study.

1.6. STATISTICAL ANALYSIS PLAN (SAP)

1.6.1. SAP OBJECTIVES

The objective of this SAP is to describe the statistical analyses to be carried out for the final analysis of this study.
1.8.2. **General Principles**

An alpha level of 0.05, and confidence intervals be set at 95% will be used for all statistical tests. Power of 0.8 was assumed when calculating sample sizes.

1.8.3. **Software**

Analyses will be carried out using SPSS, R, or Prism.

2. **Analysis**

2.1. **Study Populations**

All ICHD patients who tested positive for COVID19, on a hospital based real time reverse transcription quantitative polymerase chain reaction tests, will be included in this study.

These patients will be divided into those who had severe COVID19 (defined as respiratory support with supplemental oxygen or more, and/or a CRP of >75) and those who were able to oxygenate effectively on room air (no supplemental oxygen, or further interventions required).

2.2. **Outcomes**

2.2.1. **Primary Outcome**

The primary outcome of this study is COVID severity, as defined above in section 2.1. The effect of exposures on this outcome will be assessed in this study and has been detailed in section 2.3.
2.3. EXPOSURES

2.3.1 Primary Exposures

The primary exposures of interest are:

1) Diabetes status (collected as a yes/no categorical variable), inclusive of all variants.
2) BMI collected as a continuous variable
3) Ethnicity, defined as a categorical variable based on office of national statistics categories.
4) The Charlson Comorbidity index
5) Social deprivation will be collected using the English Index of Multiple Deprivation rank and deciles, as an ordinal variable.

2.3.2 Exploratory Exposures

Exploratory exposures of interest will include association age, sex, dialysis vintage, dialysis access, renin-angiotensin inhibition, transplant status, immunosuppression status, haemoglobin, vitamin D supplementation and blood pressure.

2.4 ANALYSIS PLAN

2.4.1 Baseline data

Incidence of COVID-19 and Severe COVID-19 will be calculated against the total dialysis population belonging to each participating haemodialysis unit, during the time frame of data collection.

Continuous variables will be summarised by mean and standard deviation, minimum and maximum. Categorical variables will be summarised by N (%).
2.4.2 Exposure effect exploration

The incidence of severe COVID between exposed and non exposed groups, as defined in sections 2.3.1 and 2.3.2 will be compared. Continuous variables will be summarised by mean and standard deviation, minimum and maximum. Categorical variables will be summarised by N (%).

2.4.3. Modelling – adjusted and unadjusted

Risk factor effects on primary outcomes (severe COVID19) will be analysed using logistic regression models. Adjustments will be made for sex, age and ethnicity.

3. DOCUMENT HISTORY

This is version 1.3 of the SAP for this study, dated 19th of December 2020, the fourth iteration of this document.
Supplementary Figure 1A: Incident cases of severe (red) and non-severe (blue) cases over time, grouped by dialysis unit and dialysis slots. Morning and Midday slots, and Midday and evening slots were grouped together to account for the risk of overlap, although this was avoided where possible. The dot represents the date of a positive PCR test conferring a diagnosis of COVID-19. The horizontal line represents the presumed incubation period of 14 days, and the vertical line represents the three day period in which infectivity would have been possible. Although certain clusters are visible, a relationship between clustering and severity is not consistent or evident.
Supplementary Figure 1B: Incident cases of severe (red) and non-severe (blue) cases over time, grouped by dialysis unit and dialysis slots. Morning and Midday slots, and Midday and evening slots were grouped together to account for the risk of overlap, although this was avoided where possible. The dot represents the date of a positive PCR test conferring a diagnosis of COVID-19. The horizontal line represents the presumed incubation period of 14 days, and the vertical line represents the three day period in which infectivity would have been possible. Although certain clusters are visible, a relationship between clustering and severity is not consistent or evident.
Supplementary Figure 1C: Incident cases of severe (red) and non-severe (blue) cases over time, grouped by dialysis unit and dialysis slots. Morning and Midday slots, and Midday and evening slots were grouped together to account for the risk of overlap, although this was avoided where possible. The dot represents the date of a positive PCR test conferring a diagnosis of COVID-19. The horizontal line represents the presumed incubation period of 14 days, and the vertical line represents the three day period in which infectivity would have been possible. Although certain clusters are visible, a relationship between clustering and severity is not consistent or evident.
Supplementary Figure 1D: Incident cases of severe (red) and non-severe (blue) cases over time, grouped by dialysis unit and dialysis slots. Morning and Midday slots, and Midday and evening slots were grouped together to account for the risk of overlap, although this was avoided where possible. The dot represents the date of a positive PCR test conferring a diagnosis of COVID-19. The horizontal line represents the presumed incubation period of 14 days, and the vertical line represents the three day period in which infectivity would have been possible. Although certain clusters are visible, a relationship between clustering and severity is not consistent or evident.
