ABSTRACT

Objective: To identify risk factors for inhospital mortality in patients with hip fractures using the Japanese Diagnosis Procedure Combination (DPC) nationwide administrative claims database.

Participants: The authors analysed a total of 80800 eligible patients aged ≥60 years with a single hip fracture (International Classification of Diseases, 10th Revision codes: S72.0 and S72.1). The DPC database includes patients treated between July and December each year.

Main outcomes: Inhospital mortality after hip fracture.

Results: The overall inhospital mortality rate after hip fractures was 3.3%. Multivariate analysis indicated that inhospital mortality was significantly associated with male gender (OR 2.12, 95% CI 1.94 to 2.31), advancing age and number of comorbidities. Significantly higher mortality was observed in those treated conservatively (OR 4.25, 95% CI 3.92 to 4.61). Surgical delays of 5 days or more were significantly associated with higher rates of inhospital mortality (OR 1.34, 95% CI 1.20 to 1.50). Inpatients with hip fractures, male gender, advancing age, high number of comorbidities, conservative treatment and the surgical delay of 5 days or more were associated with higher rates of inhospital mortality.

Conclusions: In patients with hip fractures, male gender, advancing age, high number of comorbidities, conservative treatment and the surgical delay of 5 days or more were associated with higher rates of inhospital mortality.

INTRODUCTION

Hip fracture is a serious injury related to bone fragility caused by osteoporosis, and it has emerged as a public health burden in an ageing society, such as that of Japan.¹ ³ It is estimated that the number of hip fractures worldwide will rise from 1.7 million in 1990 to 6.3 million in 2050.⁶ Recent studies have reported an increased incidence of hip fractures in Japan,³ ⁵ although the incidence is decreasing in some Western countries.⁷ ⁸ Hip fracture leads to impaired function, loss of independence and increased mortality of the patients. It has been reported that the increased mortality after hip fracture is associated with many factors, such as increasing age, comorbidity and prefracture functional disability of the patients.⁹–¹² Hip fractures are usually treated by orthopaedic surgical
Risk factors affecting inhospital mortality after hip fracture

ARTICLE SUMMARY

Strengths and limitations of this study
- We analysed a large number of patients using the Japanese DPC administrative claims database, which included approximately 40% of all the inpatient admissions to acute care hospitals in Japan.
- Complications occurring after admission are clearly differentiated with comorbidities that were already present at admission.
- This is a retrospective observational study, and the database includes information only during the hospitalisation.

METHODS

DPC database
The DPC database is a diagnosis-dominant case-mix system administered by the Ministry of Health, Labour and Welfare of Japan, and linked with a lump-sum payment system.19 All 82 university teaching hospitals in Japan are obliged to adopt the DPC system, while adoption by community hospitals is voluntary. A comprehensive survey of the DPC hospitals is conducted between 1 July and 31 December each year by the DPC Research Group, funded by the Japanese government. Detailed patient data, as well as administrative claims data, are collected for all the inpatients discharged from the participating hospitals between 1 July and 31 December each year. The number of participating hospitals increased to 818 with 2.57 million patients in 2009, which represented approximately 40% of all the inpatient admissions to acute care hospitals in Japan. Hospitals send all the anonymised data for each month to the DPC Research Group for compilation in the DPC nationwide administrative claims database and compared mortality following hip fractures between groups treated surgically or conservatively.

RESULTS

Patient background
Data of 94,139 patients with hip fractures were extracted based on ICD-10 codes. We excluded 8956 patients with open fractures or multiple fractures, 496 patients with incomplete data and 3887 patients aged <60 years. Finally, 80,800 eligible patients were included in the analysis.

Table 1 presents the patients’ characteristics. Overall, 79.1% were women. The mean (SD) age was 82.8 (8.3) years. The patients were categorised into the following four age groups: 60–69 years (n=5523), 70–79 years (n=18,618), 80–89 years (n=37,362) and ≥90 years (n=19,297). Approximately 83% (n=66,893) of patients underwent surgical treatment, while 17% (n=13,907) were treated conservatively. Hospital size was categorised into four groups according to the number of acute beds: ≤199 (13.9%), 200–399 (40.4%), 400–599 (28.6%) and ≥600 (15.0%). The proportion of patients with comorbidities at admission was as follows: malignancy (5.7%), diabetes mellitus (13.4%), cardiovascular disease; complications after admission coded with the ICD-10 codes; inhospital mortality; length of stay and hospital charges.

This study was based on a secondary analysis of the administrative claims data. The requirement for informed consent was waived because of the anonymous nature of the data. Study approval was obtained from the institutional review board at the University of Occupational and Environmental Health.

Data compilation
We retrospectively collected data of patients coded S72.0 (fracture of the neck of the femur) and S72.1 (pertrochanteric fracture) between 2007 and 2009 from the DPC database. Exclusion criteria were as follows: age <60 years, patients with open fractures or multiple fractures and incomplete data. We extracted data on age, sex, method of treatment (surgical or conservative), number of acute beds and inhospital mortality. From the comorbidities at admission, we collected data on seven factors: malignancy, diabetes mellitus, cardiovascular disease, cerebrovascular disease, lung disease, renal failure and hepatic failure.

Statistical analysis
The χ² test was used for univariate comparisons of the surgical and conservative treatment groups. Multivariate logistic regression analysis was performed to analyse the confounding effects of various factors on inhospital mortality. ORs and 95% CIs were determined. The OR of inhospital mortality in conservatively treated patients was analysed in subgroups of patients stratified according to the number of comorbidities or age. In addition, the effect of surgical delays in surgically treated patients was analysed. A p value <0.05 was considered significant. All the statistical analyses were performed using SPSS Statistics V.19.0 (IBM SPSS Inc.).
(7.6%), cerebrovascular disease (8.0%), lung disease (6.4%), renal failure (4.4%) and hepatic failure (0.8%).

### Univariate analysis of inhospital mortality

Table 2 shows the factors associated with inhospital mortality according to the univariate analysis. The overall inhospital mortality rate was 3.3% (n=2681), with the average length of stay of 38 days. Male gender, advancing age, conservative treatment and smaller hospital size were significantly associated with higher mortality. As for comorbidities, patients with malignancy, lung disease, renal failure and hepatic failure at admission exhibited higher mortality rates. In contrast, diabetes mellitus, cardiovascular disease or cerebrovascular disease did not significantly affect the mortality of the patients. The number of comorbidities at admission was positively related to the mortality rate.

### Multivariate analysis of inhospital mortality

Table 3 shows the adjusted OR and 95% CI for inhospital mortality as determined by multivariate analysis. Consistent with the univariate analysis, the inhospital mortality was significantly associated with male gender (OR 2.12 compared with female gender; p<0.001), advancing age (OR 1.57 in the 70–79 years age group, 2.28 in the 80–89 years age group and 3.51 in the ≥90 years age group compared with the 60–69 years age group; p<0.001), conservative treatment (OR 4.25 compared with the surgical treatment group; p<0.001) and number of comorbidities (OR 2.50 in patients with one comorbidity and 3.79 in those with two or more comorbidities compared with no comorbidity; p<0.001). There was no association with hospital size. We then stratified the patients into the following three groups according to the number of comorbidities: no comorbidity (n=51 544), one comorbidity (n=22 170) and two or more comorbidities (n=7086). Regardless of the number of comorbidities, conservative treatment was significantly associated with higher mortality compared with surgical treatment (figure 1A). In addition, patients with conservative treatment exhibited higher mortality even when the patients were stratified according to age (figure 1B).

We finally analysed the effect of surgical delays on inhospital mortality in patients treated surgically. The proportion of patients with delay to surgery of 5 days or more was 43.3%, and the delay was significantly associated with a higher rate of inhospital mortality (OR 1.34, 95% CI 1.20 to 1.50), while there was no significant difference in mortality among patients undergoing surgery within 4 days.

DISCUSSION

Previous studies have reported that 3.6%–6.0% of patients with hip fractures die during hospitalisation and that the 1-year mortality rate is between 10.1% and 27.3%. The reasons for the high mortality rate after hip fracture have been extensively studied. Frost et al. recently reported that men had a 2.4 times higher risk of inhospital death compared with women, and advancing age increased the risk by 2.06 times for every 10-year increase in age. Maggi et al. reported that 6-month mortality was positively associated with increasing age, comorbidity, prefracture functional disability and having surgery more than 48 h after admission. Hu et al. identified the following 12 preoperative predictors of postoperative mortality in patients with hip fracture through systematic review: advanced age, male gender, nursing home or facility residence, poor preoperative walking capacity, poor activities of daily living, higher ASA (American Society of Anesthesiologists) grading, poor mental state, multiple comorbidities, dementia or cognitive impairment, diabetes, cancer and cardiac disease.

In this study, we investigated the inhospital mortality rate after hip fractures using the Japanese DPC administrative claims database. The DPC database is equivalent in several ways to the Nationwide Inpatient Sample Database in the USA, but there is an advantage of the DPC database whereby complications occurring after admission are clearly differentiated with comorbidities that were already present at admission.

In our study, 83% of the patients underwent surgery and 17% were treated conservatively, which were similar rates to previous studies. The proportion of conservative treatment was higher than that in the Western countries, which may be due to the insurance system in Japan, which allows patients a longer hospital stay.

Overall, 3.3% of patients died during the hospitalisation. The mortality rate was slightly lower than that in previous reports. In multivariate analysis, we found that male gender, advancing age and number of comorbidities were positively and independently associated with the mortality, which is consistent with previous studies. The size of hospital as determined by the number of acute beds had no significant relationship with inhospital mortality in our study. This result may suggest that high-risk patients are not necessarily treated at large hospitals. Schilling et al. reported that decreased hospital-wide nurse staffing levels are associated with increased inhospital mortality among patients with hip fracture. In contrast, Browne et al. reported that hospital volume is not associated with decreased mortality in the treatment of hip fractures. There are various scales to represent hospital quality, so more studies may be needed to clarify the relationship between hospital quality and hip fracture mortality.

Interestingly, conservative treatment was an independent risk factor for inhospital mortality. The analysis indicated that this did not arise because of patients with higher risks being more likely to undergo conservative treatment, as patients treated conservatively exhibited more than four times higher risk for mortality even after stratification according to the number of comorbidities.
or age. The exact reason for the higher mortality in conservatively treated patients is unclear, but the patients treated surgically can start rehabilitation earlier and therefore avoid the complications caused by long-term bed rest, such as bedsores, venous thromboembolism, atelectasis and hypostatic pneumonia.

We found that surgical delays of 5 days or more were significantly associated with higher rates of inhospital mortality, which was consistent with the recent prospective cohort study by Vidan et al., showing that surgical delays longer than 5 days were associated with higher mortality and medical complication rates.

Our study has several limitations. First, this is a retrospective observational study. Thus, patient allocation was non-randomised, and the cohort of patients we analysed did not constitute random sampling. Consequently, our results are potentially biased due to unmeasured confounders. Second, the DPC-adopting hospitals are generally of large size, although the DPC database covered more than 40% of all inpatient admissions in Japan. Third, this database is for administrative claims, so recorded diagnoses may be less well validated than in planned prospective surveys. Finally, this database includes information only during the hospitalisation, and we were unable to determine the condition of patients before admission or after discharge. Despite these limitations, our study provides helpful information about the risk factors of inhospital mortality for treatment decision-making in patients with hip fractures.

CONCLUSION

This study has shown that male gender, advancing age, high number of comorbidities, conservative treatment and surgical delay were associated with higher rates of inhospital mortality in patients with hip fractures.
