Key words: cancer stage at diagnosis; case register linkage; severe mental illness; survival

Word count: 3,152

ABSTRACT

Background: There have been inconsistent research results reported for the effects of prior serious mental disorders on cancer mortality and morbidity.

Methods: Using the anonymised linkage between a regional monopoly secondary mental health service provider in southeast London and a population-based cancer register, a historical cohort study was constructed. Comparisons between people with and without specific psychiatric diagnosis in the same residence area for risks of advanced stage of cancer at diagnosis and general survival after cancer diagnosed were analysed using logistic and Cox models.

Results: A total of 28,477 cancer cases aged 15+ years old with stage of cancer recorded at diagnosis were identified. Among these, 2,206 subjects had been previously assessed or treated in secondary mental healthcare before their cancer diagnosis and 125 for severe mental illness (schizophrenia, schizoaffective, or bipolar disorders). No associations were found between specific mental disorder diagnoses and beyond-local spread of cancer at presentation. However, people with severe mental disorders, depression, dementia, and substance use disorders had significantly worse survival after cancer diagnosis, independent of cancer stage at diagnosis and other potential confounders.

Conclusions: Previous findings of associations between mental disorders and cancer mortality are more likely to be accounted for by differences in survival after cancer diagnosis rather than by delayed diagnosis.

Strengths and limitations of this study:

Main strengths:

- Longitudinal study design with a data linkage between two case register systems in London, UK
- Mortality information was retrieved from the national registry of death certificates in UK.

Limitations:

- The completeness rate of cancer stage was about 65%, which is within the range reported by other cancer registries in England and did not differ for most of the mental disorder groups of research interest compared to the remaining population.
- Lack of lifestyle factors (smoking, drinking, diet, obesity, and physical activities) for confounding control in survival analysis
- Small cancer case numbers of some specific mental disorders did not permit restricting the sample for sensitivity analyses. Also, size of the linked sample also did not allow further analyses of individual cancer diagnoses.

INTRODUCTION

Numerous studies have indicated a higher risk of all-cause mortality and shorter life expectancy for people with severe mental illness (SMI), including schizophrenia, bipolar disorder, schzoaffecive disorder, and sometimes depressive disorders.¹⁻⁸ The profile of causes of death among people with SMI is not substantially different from that in general population, although some specific patterns of death have been suggested, differing by sex, age group, and mental disorder diagnosis.^{3 5-7 9-13} In recent decades, cardiovascular disease, stroke, respiratory diseases, suicide, and cancer have remained the leading causes.^{3 5-7 9-13}

A recent population-based study revealed that men with psychiatric admissions before cancer registration had a significantly worse survival, especially for those with depressive disorders, neurotic and adjustment disorders, and alcohol-related or other substance use disorders.¹⁴ Results from three population-based cohort studies showed significantly increased cancer mortality among people with schizophrenia for both genders,^{5 9 15} but some other studies reported that it occurred in men^{7 13 16 17} or women only.¹⁸ However, other studies found no association with cancer mortality for SMI as a whole or schizophrenia specifically^{7 13 16 17} and even a reduced risk was reported in one study.⁶ Depression has also been found to be associated with an increase in cancer mortality.¹⁹ Studies of the incidence of cancer in people with SMI have principally focused on schizophrenia with varying results, including reduced total cancer incidence,^{18 20-25} no difference,²⁶⁻²⁹ or increased risk.³⁰ A meta-analysis pooling eight studies concluded no association between schizophrenia and incidence of cancer.²⁷ A history of depression or alcohol-related or substance use disorders has been associated with increased cancer,³¹ but inconsistent findings have been found for bipolar disorder,^{32 33} dementia,^{15 18 34} and null for schizoaffecive disorder.²⁹ Evidence on the role of mental disease as a comorbidity factor in cancer is therefore still far from conclusive, but tends to indicate cancer

1
2 incidence that is either reduced or not different, and cancer mortality that is increased.^{32 33}

5
6

7 Thinking of how to solve the puzzle shown on conflicting research results and effects of mental
8 disorders to cancer prognosis, there are two key research questions to be answered. First, to what
9 extent might the reduced recognition of early cancer symptoms in people with mental disorders
10 influence the stage of cancer at diagnosis?^{33 35-37} And, secondly, what is the role of mental disorders
11 on mortality after cancer diagnosis if the issue of later presentation of cancer could be ruled out?
12 Then, an influence of mental disorders on cancer mortality in the absence of a clear effect on
13 underlying risk could be explained by differences in treatment access, response and adherence, as
14 previously raised by Kisely and colleagues.^{15 38} Utilising a data linkage between a large secondary
15 mental healthcare case register in southeast London and the regional cancer registry, we sought to
16 investigate associations between mental disorder and both disease stage at cancer diagnosis and
17 subsequent survival.

35 MATERIALS AND METHODS

36 **The South London and Maudsley NHS Foundation Trust (SLAM) Biomedical Research Centre** 37 38 **(BRC) Case Register**

39 The SLAM BRC Case Register was used to provide data on mental disorders for the current study.
40
41 SLAM is the near-monopoly provider of comprehensive secondary mental health services for a
42 geographic catchment consisting of four London boroughs (Southwark, Lambeth, Lewisham, and
43 Croydon) with approximately 1.23 million residents. Clients' records for all the services provided by
44 SLAM were electronised in 2006. In 2008, the Clinical Record Interactive Search (CRIS) system was
45 developed as a platform for investigators to search and access full but anonymised clinical data from
46 the fully electronic health records system in SLAM for research purposes. All people receiving

1
2
3 SLAM care for psychiatric assessments and / or treatment were included in the database. The
4
5 demographic characteristics and clinical profiles of the Case Register population have been fully
6
7 described elsewhere.³⁹ Ethical approval as an anonymised data resource for secondary analyses was
8
9 received from Oxfordshire REC C in 2008 (reference number 08/H0606/71).
10
11

12 13 14 **Thames Cancer Registry (TCR)**

15
16 At the time of the study, TCR was the largest of eight population-based cancer registries in England,
17
18 covering a population of 12 million residents in London, Kent, Surry, and Sussex. Registration was
19
20 initiated by pathology reports and clinical records from hospitals and information on death
21
22 certificates received from the NHS Central Register through the Office of National Statistics in 1999.
23
24 When cancer is recorded as the main or contributing cause of death in the Part 1 section, the
25
26 certificate is routinely sent to the regional cancer registry. Further information on demographic,
27
28 clinical details, and treatments received within the first six months after cancer diagnosis was
29
30 retrieved from hospitals or hospital databases by trained data collection officers. A central regional
31
32 database was maintained with data added continuously and robust data quality controls. To avoid
33
34 double counting, information about new tumors was cross-checked against existing registered cases.
35
36 Cancer registration and cancer surveillance take place in English registries under provisions of
37
38 Section 251 of the Health and Social Care Act and this permission is reviewed annually. The Thames
39
40 Cancer Registry was assessed to be more than 95% complete in 2001-2007 and considered as of
41
42 sufficient quality for cancer outcomes analyses.^{40 41}

52 **Anonymised process of data linkage**

53
54 Data from CRIS and TCR for residents in the SLAM geographic catchment were linked using an
55
56 anonymisation process by the Health Research Support Service (HRSS) Pilot Programme which was
57
58
59
60

operated by the Department of Health as part of the NHS Research Capability Programme in the UK. Memoranda of Understanding were signed between SLAM and TCR through HRSS, which in turn designed and created an infrastructure to provide a safe and confidential platform for health research. With HRSS as the “trusted third party”, the linkage was performed using a series of identifiers including the NHS number and was then irreversibly de-identified, replacing the NHS number with an encrypted HRSS identification (HRSS id). The initial sample selected for analysis comprised individuals on the TCR dataset within SLAM coverage area. Thus, a retrospective cohort study of people under the care of secondary mental health services could be performed.

Covariates included

Mental disorder diagnoses were identified from two sources within CRIS: i) a primary psychiatric diagnosis (Axis 1a) categorised by ICD-10 code (a structured field, compulsory for completion by services, with a specific date in the electronic clinical records system); and ii) a supplementary natural language processing application developed using General Architecture for Text Engineering (GATE) software which extracts text strings relating to a diagnosis statement in correspondence fields. The first diagnoses from either or both sources were then categorised into the following groupings (ICD codes): dementia (F00-03), substance use disorders (F10-19), schizophrenia (F20), schizoaffective disorder (F25), bipolar disorder (F31), depressive disorders (F32-33), anxiety disorders (F40-42), and personality disorders (F60-61). Severe mental illness (SMI) was defined as a diagnosis of schizophrenia (F20), schizoaffective disorder (F25), or bipolar disorder (F31). In the TCR data, tumor stage at presentation of cancer was routinely extracted from an individual’s medical records and categorised as follows: “local” (stage 1), “extension beyond the organ of origin” (stage 2), “regional lymph node involvement” (stage 3), and “metastasis” (stage 4). Cases without sufficient information about disease stage were classified as “not known”. Date of cancer diagnosis, date of

1
2
3 birth, sex, type of cancer, primary care trust (geographic area), and ethnic group were also routinely
4 collected in TCR and were used as covariates. In addition, the income domain of the index of
5 multiple deprivations in 2007 was derived on the basis of the residential postcode.⁴²
6
7
8
9

10 11 **Statistical analysis**

12 All the cancer cases diagnosed in the period from 1999 to 2008 in residents of the catchment area of
13 four London boroughs under SLAM service coverage were included in current analyses. Through the
14 linkage performed by HRSS, any cancer detected after a contact with SLAM was marked. If multiple
15 tumors were registered in one person, only the first cancer onset was considered. Their primary
16 psychiatric diagnosis given in SLAM services before the cancer was identified (if any) as the major
17 exposure of interest in current analyses. Stage of disease at cancer diagnosis was categorised into two
18 groups: i) early stage with no spread or only local extension beyond the organ of origin (localized
19 stage), and ii) late stages with regional lymph node involvement or metastasis (advanced stage). This
20 was treated as a binary dependent variable and was modeled against mental disorder diagnoses by
21 logistic regressions. Cox regression models were then assembled to estimate associations between
22 mental disorder and survival after cancer diagnosis. The duration of follow up was defined as the
23 period from cancer diagnosis to the date of death (any cause) or the end of the follow-up period (12
24 Jun, 2010), provided by TCR. Age at cancer diagnosis, gender, type of cancer, year of cancer
25 diagnosis, primary care trust (geographic area), ethnic groups, deprivation score for income, and
26 stage at cancer diagnosis were treated as potential confounders, where appropriate. Area-level
27 deprivation score for income was classified into quintiles, with the 1st quintile representing the most
28 affluent areas and applied as the reference group in modeling. Stata/IC 12.1 software for Windows
29 (Stata Corporation, 2011) was used for all the analyses.

RESULTS

The study sample

A total of 43,746 cancer cases were identified from TCR records. No significant associations were found between psychiatric diagnosis and missing stage data apart from a higher proportion of missing data in people with dementia (46.8%) compared to the remainder (35.0%). After the exclusion of people without confirmed cancer stage information and those younger than 15 years old at cancer diagnosis (n = 101), with missing date of birth (n = 1) or date of cancer diagnosis (n = 1), 28,477 cases (65.1%) remained and were included in our analyses. Among them, 55.3% were female. Up to the end of 2008, a total of 2,206 of these cancer cases had received any SLAM service (i.e. were present on the CRIS database), and 125 of these had received an SMI diagnosis prior to their cancer diagnosis.

Factors associated with extent of disease at cancer diagnosis

Of the analysed sample of cancer cases, 64.2% (n = 18,290) were diagnosed with localized stage of disease. Descriptive characteristics of the sample by stage at cancer diagnosis are presented in Table 1. Subjects with advanced stage of cancer at diagnosis were older and more likely to be male (both p values < .001), and there was significant variation by cancer type, year of diagnosis, primary care trust, and ethnic group (all p values < .001), although no clear linear trend for socio-economic deprivation was evident (details not shown).

Mental disorder and stage at cancer diagnosis

Associations between preceding mental disorders and stage at cancer diagnosis are summarised in Table 2. In summary, findings were null and there was no evidence of an association with any

1
2
3 diagnostic group after adjustment for age, gender, type of cancer, year of cancer diagnosis, primary
4 care trust, ethnicity, and deprivation score for income.

22

23 24 **DISCUSSION**

25 26 **Main findings**

27
28 This linkage between a population-based cancer register and a near-monopoly secondary mental
29 health service provider with a geographic catchment of approximately 1.23 million residents
30 provided a sufficiently large sample for this investigation. The key findings were that people who had
31 been diagnosed with specific mental disorders in the secondary mental health service were not more
32 likely to have cancer with advanced stage at diagnosis, but that many of the mental disorder groups
33 had worse subsequent survival. This latter finding was significant for SMI as a whole, and for
34 schizophrenia and schizoaffective disorder individually, as well as for those with diagnoses of
35 depression, dementia, and substance use disorders prior to the cancer diagnosis. The stage of cancer
36 at diagnosis in people with mental disorders did not explain their worse subsequent survival.

42
43
44
45
46
47
48
49
50
51

52 53 **Advantages and limitations**

54 The study described here benefited from the large size of the two data sources. The linkage allowed
55 the longitudinal observation of a substantial number of cases with mental disorder diagnoses who had
56
57
58
59
60

1
2 subsequently developed cancer, and comparison group of the remaining people with cancer diagnoses
3
4 from the same geographic catchment area. Ascertainment of vital status and deaths were achieved by
5
6 linkage to death certificates provided electronically from the Office for National Statistics.
7
8

9
10 Limitations include a fairly large proportion with missing data on cancer stage (34.7%). This
11
12 completeness level is within the range reported by other English registries and represents the data
13
14 available to the registration process. These levels have been improving with the receipt of electronic
15
16 pathology data from hospitals. Importantly, the proportions with missing stage data did not differ for
17
18 most of the mental disorder groups of primary interest compared to the remaining population (the
19
20 only exception being dementia) and principal findings are therefore unlikely to have been biased by
21
22 availability of stage information. The other issue was the lack of lifestyle factors for smoking,
23
24 drinking, diet, obesity, and physical activities in our dataset, which made further confounding control
25
26 inapplicable. Another limitation was that some of the required data on mental disorders were drawn
27
28 from years when there was less than full information, since electronic records became comprehensive
29
30 across all SLAM services during 2006; however, case numbers did not permit restricting the sample
31
32 any further for sensitivity analyses. The size of the linked sample also did not permit analyses of
33
34 individual cancer diagnoses. Besides, the significant finding of schizoaffective disorder for survival
35
36 after cancer diagnosis in Table 3 was based on 5 cases only.
37
38
39
40
41
42
43
44

45 **Comparisons with related studies**

46
47 In the relatively scarce literature about potentially delayed cancer diagnoses among people with
48
49 mental disorders, the most recent published study reported a significantly higher proportion of
50
51 metastasis at cancer presentation for psychiatric patients comparing to general population (7.1%
52
53 versus 6.1%) in Western Australia, especially for the cancer of breast and lung.¹⁵ A US study, linking
54
55 Surveillance, Epidemiology and End Results data to Medicare, found that people without mental
56
57
58
59
60

1
2
3 disorder were slightly more likely to have an earlier detection of colon cancer than people who had
4 any mental disorder (53.3% versus 49.7%), although it was partially contributed by higher proportion
5 with unknown stage when colon cancer diagnosed (6.2% versus 14.6%). The frequency of diagnosis
6 at autopsy for colon cancer among people without mental disorder was also significantly lower than
7 cases (1.1% versus 4.4%).³⁵ However, these two studies did not adjust for potential confounders in
8 their analyses, especially for type of cancer.^{15 35} Another study focusing on breast cancer with
9 confounders adjusted found that a history of major depression was associated with a delayed
10 diagnosis of breast cancer representing an almost ten-fold increased risk, but the opposite direction of
11 association was found for phobia.⁴³ Although we should have sufficient statistical power to identify
12 the differences, our null findings for people undergoing assessment and treatment in secondary
13 mental health services made the issue about delayed diagnosis of cancer among people with mental
14 illness still inconclusive. Although potential explanation about specific psychological characteristics
15 of dispositional insensitivity to threat (if the relation really exists) was found to be associated with
16 delayed help seeking for symptoms of rectal cancer,³⁶ further in-depth investigations on the effect of
17 mental disorders to physical healthcare utilisations is needed.

36
37
38
39
40 On the issue of survival for people with mental disorders after cancer diagnosis, a previous study of a
41 population-based male Swedish cohort with psychiatric admissions before cancer diagnosis by
42 registration found significantly worse survival, especially for those who had had depressive disorders,
43 neurotic and adjustment disorders, and alcohol-related or other substance use disorders.¹⁴ With a
44 similar study design, Kisley *et al.* identified a significantly elevated risk of cancer mortality for
45 people with psychiatric disorder in Canada.³⁸ Advanced analyses exploring the reasons for elevated
46 all-cause mortality following cancer diagnosis were also reported for people with known mental
47 disorders in Western Australia, finding reduced likelihood of surgery after diagnosis of colorectal,

1
2 breast, and cervical cancers in people with mental disorders and less radiotherapy or chemotherapy
3 receipt.¹⁵ The US linkage between Surveillance, Epidemiology and End Results data and Medicare
4
5 found that receipt of colon cancer treatment (any treatment at all stages or chemotherapy at stage 3
6
7 only) was significantly lower for people with preexisting any mental disorder, mood disorder,
8
9 psychiatric disorder, and dementia.³⁵ Our study provided additional support to the finding that,
10
11 although the stage of diagnosis for cancer of people with mental illness was not more advanced, these
12
13 people were still at higher risk of death comparing to their counterparts without mental illness. The
14
15 underlying reasons might differ by medical care system in countries. Further details about the
16
17 treatment trajectories after cancer diagnosis for people with mental disorder are needed for advanced
18
19 studies.

22
23
24
25
26
27

28 **Implications and direction for future studies**

29
30 The wider question about cancer risk and outcome in people with mental disorders has received
31
32 considerable attention over the years, although studies have principally investigated overall
33
34 cancer-related mortality or cancer incidence. While findings about cancer screening uptake rates
35
36 among people with SMI were inconsistent across and within countries,⁴⁴ one possible reason for
37
38 reasonably consistent raised cancer-related mortality in people with mental disorders but inconsistent
39
40 evidence for raised cancer incidence is that the mortality is explained by delays in presentation rather
41
42 than increased risk. However, we found no evidence that prior mental disorder was associated with
43
44 more advanced stage of cancer at diagnosis, a measure of delay in presentation, which might because
45
46 that, in UK, since 2003, GPs have been incentivised under the guide of Quality and Outcomes
47
48 Framework⁴⁵ to offer regular physical health reviews to people with long-term mental health
49
50 problems, including preventative cancer screening appropriate to age and gender since 2006.
51
52
53
54
55
56
57
58
59
60

1
2
3 Instead, consistent with other findings,^{14 15 35 38} we found an association with worse survival after
4 cancer diagnosis that was not explained by stage at presentation. This suggests that effects of mental
5 disorder on cancer mortality primarily exert themselves after the diagnosis. Causal pathways might
6 include reduced access to medical treatment and care, differing decisions about or tolerance of
7 intensive regimes, and the influence of other health problems or drug effects on survival. Also, there
8 might be differences between cancers on the impact to survival for early diagnosis, but there were
9 insufficient data to analyze such differences among types of cancer. Clearly the components of such
10 disadvantage require further evaluation. A greater understanding is needed of levels of utilisation of
11 healthcare services and potential barriers to this among people with mental illness, including the
12 extent to which this is present across individual cancer diagnoses and to which it is accounted for by
13 the specific symptoms of the mental disorders themselves, by accompanying social disadvantage, or
14 potentially by stigma. Also worthy of further evaluation is the potential impact that mental healthcare
15 could have on improving physical health and other indirect influences of mental disorders on adverse
16 health outcomes.

Table 1. Descriptive statistics of cancer patients in southeast London by stage at cancer presentation from 1999 to 2008

Variables	Number (%) / Mean \pm SD		
	Subjects with stage at cancer diagnosis (N = 28,477)		
	All cases (N = 43,454)	Localized stage (n = 18,290)	Advanced stage (n = 10,187)
Age at cancer diagnosis (yrs)	63.31 \pm 17.96	60.38 \pm 19.15	66.80 \pm 14.29
Gender			
Female	32,242 (53.49)	10,257 (56.08)	5,490 (53.89)
Male	20,212 (46.51)	8,033 (43.92)	4,697 (46.11)
Type of cancer			
Lung	5,286 (12.16)	1,724 (9.43)	2,068 (20.30)
Bladder	1,170 (2.69)	636 (3.48)	111 (1.09)
Breast	5,943 (13.68)	2,592 (14.17)	1,833 (17.99)
Skin	2,189 (5.04)	1,548 (8.46)	93 (0.91)
Prostate	4,975 (11.45)	2,657 (14.53)	634 (6.22)
Corpus Uteri	804 (1.85)	485 (2.65)	121 (1.19)
Colorectal	3,979 (9.16)	1,441 (7.88)	1,531 (15.03)
Others	19,108 (43.97)	7,207 (39.40)	3,796 (37.26)

Ethnicity

White	26,055 (59.96)	10,766 (58.86)	6,797 (66.72)
Black	5,080 (11.69)	2,293 (12.54)	1,293 (12.69)
East Asian	541 (1.24)	222 (1.21)	135 (1.33)
South Asian	804 (1.85)	258 (1.41)	173 (1.70)
Others/Unknown/mixed	10,974 (25.25)	4,751 (25.98)	1,789 (17.56)

Deprivation score (income)

1 st quintile	2,465 (5.67)	709 (3.88)	417 (4.09)
2 nd quintile	3,308 (7.61)	1,098 (6.00)	629 (6.17)
3 rd quintile	6,520 (15.00)	2,844 (15.55)	1,355 (13.30)
4 th quintile	14,114 (32.48)	6,130 (33.52)	3,308 (32.47)
5 th quintile	17,047 (39.23)	7,509 (41.06)	4,478 (43.96)

Table 2. Associations between previous diagnosis received in secondary mental healthcare and stage at cancer diagnosis (N = 28,477)

Variables	Cancer Stage at Diagnosis		Unadjusted odds ratio for advanced cancer stage (95% CI)	Age- and gender-adjusted odds ratio for advanced cancer stage (95% CI)	Fully adjusted odds ratio for advanced cancer stage ^b (95% CI)

ABSTRACT

Background: There have been inconsistent research results reported for the effects of prior serious mental disorders on cancer mortality and morbidity.

Methods: Using the anonymised linkage between a regional monopoly secondary mental health service provider in southeast London and a population-based cancer register, a historical cohort study was constructed. Comparisons between people with and without specific psychiatric diagnosis in the same residence area for risks of advanced stage of cancer at diagnosis and general survival after cancer diagnosed were analysed using logistic and Cox models.

Results: A total of 28,477 cancer cases aged 15+ years old with stage of cancer recorded at diagnosis were identified. Among these, 2,206 subjects had been previously assessed or treated in secondary mental healthcare before their cancer diagnosis and 125 for severe mental illness (schizophrenia, schizoaffective, or bipolar disorders). No associations were found between specific mental disorder diagnoses and beyond-local spread of cancer at presentation. However, people with severe mental disorders, depression, dementia, and substance use disorders had significantly worse survival after cancer diagnosis, independent of cancer stage at diagnosis and other potential confounders.

Conclusions: Previous findings of associations between mental disorders and cancer mortality are more likely to be accounted for by differences in survival after cancer diagnosis rather than by delayed diagnosis.

Strengths and limitations of this study:

Main strengths:

- Longitudinal study design with a data linkage between two case register systems in London, UK
- Mortality information was retrieved from the national registry of death certificates in UK.

Limitations:

- The completeness rate of cancer stage was about 65%, which is within the range reported by other cancer registries in England and did not differ for most of the mental disorder groups of research interest compared to the remaining population.
- Lack of lifestyle factors (smoking, drinking, diet, obesity, and physical activities) for confounding control in survival analysis
- Small cancer case numbers of some specific mental disorders did not permit restricting the sample for sensitivity analyses. Also, size of the linked sample also did not allow further analyses of individual cancer diagnoses.

INTRODUCTION

Numerous studies have indicated a higher risk of all-cause mortality and shorter life expectancy for people with severe mental illness (SMI), including schizophrenia, bipolar disorder, schzoaffecive disorder, and sometimes depressive disorders.¹⁻⁸ The profile of causes of death among people with SMI is not substantially different from that in general population, although some specific patterns of death have been suggested, differing by sex, age group, and mental disorder diagnosis.^{3 5-7 9-13} In recent decades, cardiovascular disease, stroke, respiratory diseases, suicide, and cancer have remained the leading causes.^{3 5-7 9-13}

A recent population-based study revealed that men with psychiatric admissions before cancer registration had a significantly worse survival, especially for those with depressive disorders, neurotic and adjustment disorders, and alcohol-related or other substance use disorders.¹⁴ Results from three population-based cohort studies showed significantly increased cancer mortality among people with schizophrenia for both genders,^{5 9 15} but some other studies reported that it occurred in men^{7 13 16 17} or women only.¹⁸ However, other studies found no association with cancer mortality for SMI as a whole or schizophrenia specifically^{7 13 16 17} and even a reduced risk was reported in one study.⁶ Depression has also been found to be associated with an increase in cancer mortality.¹⁸ Studies of the incidence of cancer in people with SMI have principally focused on schizophrenia with varying results, including reduced total cancer incidence,^{19 20-25} no difference,²⁶⁻²⁹ or increased risk.³⁰ A meta-analysis pooling eight studies concluded no association between schizophrenia and incidence of cancer.²⁷ A history of depression or alcohol-related or substance use disorders has been associated with increased cancer,³¹ but inconsistent findings have been found for bipolar disorder,^{32 33} dementia,^{15 18 34} and null for schizoaffecive disorder.²⁹ Evidence on the role of mental disease as a comorbidity factor in cancer is therefore still far from conclusive, but tends to indicate cancer

1
2 incidence that is either reduced or not different, and cancer mortality that is increased.^{32 33}
3
4
5
6

7 Thinking of how to solve the puzzle shown on conflicting research results and effects of mental
8 disorders to cancer prognosis, there are two key research questions to be answered. First, to what
9 extent might the reduced recognition of early cancer symptoms in people with mental disorders
10 influence the stage of cancer at diagnosis?^{33 35-37} And, secondly, what is the role of mental disorders
11 on mortality after cancer diagnosis if the issue of later presentation of cancer could be ruled out?
12 Then, an influence of mental disorders on cancer mortality in the absence of a clear effect on
13 underlying risk could be explained by differences in treatment access, response and adherence, as
14 previously raised by Kisely and colleagues.^{15 38} Utilising a data linkage between a large secondary
15 mental healthcare case register in southeast London and the regional cancer registry, we sought to
16 investigate associations between mental disorder and both disease stage at cancer diagnosis and
17 subsequent survival.

35 MATERIALS AND METHODS

36 **The South London and Maudsley NHS Foundation Trust (SLAM) Biomedical Research Centre** 37 38 **(BRC) Case Register**

39 The SLAM BRC Case Register was used to provide data on mental disorders for the current study.
40
41 SLAM is the near-monopoly provider of comprehensive secondary mental health services for a
42 geographic catchment consisting of four London boroughs (Southwark, Lambeth, Lewisham, and
43 Croydon) with approximately 1.23 million residents. Clients' records for all the services provided by
44 SLAM were electronised in 2006. In 2008, the Clinical Record Interactive Search (CRIS) system was
45 developed as a platform for investigators to search and access full but anonymised clinical data from
46 the fully electronic health records system in SLAM for research purposes. All people receiving
47

1
2
3 SLAM care for psychiatric assessments and / or treatment were included in the database. The
4 demographic characteristics and clinical profiles of the Case Register population have been fully
5 described elsewhere.³⁹ Ethical approval as an anonymised data resource for secondary analyses was
6 received from Oxfordshire REC C in 2008 (reference number 08/H0606/71).
7
8
9

14 **Thames Cancer Registry (TCR)**

16
17 At the time of the study, TCR was the largest of eight population-based cancer registries in England,
18 covering a population of 12 million residents in London, Kent, Surry, and Sussex. Registration was
19 initiated by pathology reports and clinical records from hospitals and information on death
20 certificates received from the NHS Central Register through the Office of National Statistics in 1999.
21
22 When cancer is recorded as the main or contributing cause of death in the Part 1 section, the
23 certificate is routinely sent to the regional cancer registry. Further information on demographic,
24 clinical details, and treatments received within the first six months after cancer diagnosis was
25 retrieved from hospitals or hospital databases by trained data collection officers. A central regional
26 database was maintained with data added continuously and robust data quality controls. To avoid
27 double counting, information about new tumors was cross-checked against existing registered cases.
28
29 Cancer registration and cancer surveillance take place in English registries under provisions of
30 Section 251 of the Health and Social Care Act and this permission is reviewed annually. The Thames
31 Cancer Registry was assessed to be more than 95% complete in 2001-2007 and considered as of
32 sufficient quality for cancer outcomes analyses.^{40 41}

52 **Anonymised process of data linkage**

53
54 Data from CRIS and TCR for residents in the SLAM geographic catchment were linked using an
55 anonymisation process by the Health Research Support Service (HRSS) Pilot Programme which was
56
57
58
59
60

operated by the Department of Health as part of the NHS Research Capability Programme in the UK. Memoranda of Understanding were signed between SLAM and TCR through HRSS, which in turn designed and created an infrastructure to provide a safe and confidential platform for health research. With HRSS as the “trusted third party”, the linkage was performed using a series of identifiers including the NHS number and was then irreversibly de-identified, replacing the NHS number with an encrypted HRSS identification (HRSS id). The initial sample selected for analysis comprised individuals on the TCR dataset within SLAM coverage area. Thus, a retrospective cohort study of people under the care of secondary mental health services could be performed.

Covariates included

Mental disorder diagnoses were identified from two sources within CRIS: i) a primary psychiatric diagnosis (Axis 1a) categorised by ICD-10 code (a structured field, compulsory for completion by services, with a specific date in the electronic clinical records system); and ii) a supplementary natural language processing application developed using General Architecture for Text Engineering (GATE) software which extracts text strings relating to a diagnosis statement in correspondence fields. The first diagnoses from either or both sources were then categorised into the following groupings (ICD codes): dementia (F00-03), substance use disorders (F10-19), schizophrenia (F20), schizoaffective disorder (F25), bipolar disorder (F31), depressive disorders (F32-33), anxiety disorders (F40-42), and personality disorders (F60-61). Severe mental illness (SMI) was defined as a diagnosis of schizophrenia (F20), schizoaffective disorder (F25), or bipolar disorder (F31). In the TCR data, tumor stage at presentation of cancer was routinely extracted from an individual’s medical records and categorised as follows: “local” (stage 1), “extension beyond the organ of origin” (stage 2), “regional lymph node involvement” (stage 3), and “metastasis” (stage 4). Cases without sufficient information about disease stage were classified as “not known”. Date of cancer diagnosis, date of

1
2
3 birth, sex, type of cancer, primary care trust (geographic area), and ethnic group were also routinely
4
5 collected in TCR and were used as covariates. In addition, the income domain of the index of
6
7 multiple deprivations in 2007 was derived on the basis of the residential postcode.⁴²
8
9

10 11 **Statistical analysis**

12
13 All the cancer cases diagnosed in the period from 1999 to 2008 in residents of the catchment area of
14
15 four London boroughs under SLAM service coverage were included in current analyses. Through the
16
17 linkage performed by HRSS, any cancer detected after a contact with SLAM was marked. If multiple
18
19 tumors were registered in one person, only the first cancer onset was considered. Their primary
20
21 psychiatric diagnosis given in SLAM services before the cancer was identified (if any) as the major
22
23 exposure of interest in current analyses. Stage of disease at cancer diagnosis was categorised into two
24
25 groups: i) early stage with no spread or only local extension beyond the organ of origin (localized
26
27 stage), and ii) late stages with regional lymph node involvement or metastasis (advanced stage). This
28
29 was treated as a binary dependent variable and was modeled against mental disorder diagnoses by
30
31 logistic regressions. Cox regression models were then assembled to estimate associations between
32
33 mental disorder and survival after cancer diagnosis. The duration of follow up was defined as the
34
35 period from cancer diagnosis to the date of death (any cause) or the end of the follow-up period (12
36
37 Jun, 2010), provided by TCR. Age at cancer diagnosis, gender, type of cancer, year of cancer
38
39 diagnosis, primary care trust (geographic area), ethnic groups, deprivation score for income, and
40
41 stage at cancer diagnosis were treated as potential confounders, where appropriate. Area-level
42
43 deprivation score for income was classified into quintiles, with the 1st quintile representing the most
44
45 affluent areas and applied as the reference group in modeling. Stata/IC 12.1 software for Windows
46
47 (Stata Corporation, 2011) was used for all the analyses.

RESULTS

The study sample

A total of 43,746 cancer cases were identified from TCR records. Among them, 15,166 subjects (34.7%) had no information about their stage of cancer at diagnosis. No significant associations were found between psychiatric diagnosis and missing cancer stage data apart from a higher proportion of missing data in people with dementia (46.8%) compared to the remainder (35.0%). After the exclusion of people without confirmed cancer stage information and those younger than 15 years old at cancer diagnosis (n = 101), with missing date of birth (n = 1) or date of cancer diagnosis (n = 1), 28,477 cases (65.1%) remained and were included in our analyses. Among them, 55.3% were female. Up to the end of 2008, a total of 2,206 of these cancer cases had received any SLAM service (i.e. were present on the CRIS database), and 125 of these had received an SMI diagnosis prior to their cancer diagnosis.

Factors associated with extent of disease at cancer diagnosis

Of the analysed sample of cancer cases, 64.2% (n = 18,290) were diagnosed with localized stage of disease. Descriptive characteristics of the sample by stage at cancer diagnosis are presented in Table 1. Subjects with advanced stage of cancer at diagnosis were older and more likely to be male (both p values < .001), and there was significant variation by cancer type, year of diagnosis, primary care trust, and ethnic group (all p values < .001), although no clear linear trend for socio-economic deprivation was evident (details not shown).

Mental disorder and stage at cancer diagnosis

Associations between preceding mental disorders and stage at cancer diagnosis are summarised in Table 2. In summary, findings were null and there was no evidence of an association with any

1
2
3 diagnostic group after adjustment for age, gender, type of cancer, year of cancer diagnosis, primary
4 care trust, ethnicity, and deprivation score for income.
5
6
7
8

9 10 **Mental disorder and survival after cancer diagnosis**

11 Associations between mental disorders and survival after cancer diagnosis are summarised in Table 3.
12
13 SMI as a whole (and schizophrenia and schizoaffective disorder individually), depression, dementia,
14 and substance use disorders were associated with worse survival after cancer diagnosis in fully
15 adjusted models with relatively little attenuation following adjustment for stage at cancer diagnosis.

22

23 24 **DISCUSSION**

25 26 **Main findings**

27 This linkage between a population-based cancer register and a near-monopoly secondary mental
28 health service provider with a geographic catchment of approximately 1.23 million residents
29 provided a sufficiently large sample for this investigation. The key findings were that people who had
30 been diagnosed with specific mental disorders in the secondary mental health service were not more
31 likely to have cancer with advanced stage at diagnosis, but that many of the mental disorder groups
32 had worse subsequent survival. This latter finding was significant for SMI as a whole, and for
33 schizophrenia and schizoaffective disorder individually, as well as for those with diagnoses of
34 depression, dementia, and substance use disorders prior to the cancer diagnosis. The stage of cancer
35 at diagnosis in people with mental disorders did not explain their worse subsequent survival.

42
43
44
45
46
47
48
49
50
51

52 53 **Advantages and limitations**

54 The study described here benefited from the large size of the two data sources. The linkage allowed
55 the longitudinal observation of a substantial number of cases with mental disorder diagnoses who had
56
57
58
59
60

1
2 subsequently developed cancer, and comparison group of the remaining people with cancer diagnoses
3
4 from the same geographic catchment area. Ascertainment of vital status and deaths were achieved by
5
6 linkage to death certificates provided electronically from the Office for National Statistics.
7
8

9
10 Limitations include a fairly large proportion with missing data on cancer stage (34.7%). This
11
12 completeness level is within the range reported by other English registries and represents the data
13
14 available to the registration process. These levels have been improving with the receipt of electronic
15
16 pathology data from hospitals. Importantly, the proportions with missing stage data did not differ for
17
18 most of the mental disorder groups of primary interest compared to the remaining population (the
19
20 only exception being dementia) and principal findings are therefore unlikely to have been biased by
21
22 availability of stage information. The other issue was the lack of lifestyle factors for smoking,
23
24 drinking, diet, obesity, and physical activities in our dataset, which made further confounding control
25
26 inapplicable. Another limitation was that some of the required data on mental disorders were drawn
27
28 from years when there was less than full information, since electronic records became comprehensive
29
30 across all SLAM services during 2006; however, case numbers did not permit restricting the sample
31
32 any further for sensitivity analyses. The size of the linked sample also did not permit analyses of
33
34 individual cancer diagnoses. Besides, the significant finding of schizoaffective disorder for survival
35
36 after cancer diagnosis in Table 3 was based on 5 cases only.
37
38
39
40
41
42
43
44

45 **Comparisons with related studies**

46
47 In the relatively scarce literature about potentially delayed cancer diagnoses among people with
48
49 mental disorders, the most recent published study reported a significantly higher proportion of
50
51 metastasis at cancer presentation for psychiatric patients comparing to general population (7.1%
52
53 versus 6.1%) in Western Australia, especially for the cancer of breast and lung.¹⁵ A US study, linking
54
55 Surveillance, Epidemiology and End Results data to Medicare, found that people without mental
56
57
58
59
60

1
2
3 disorder were slightly more likely to have an earlier detection of colon cancer than people who had
4 any mental disorder (53.3% versus 49.7%), although it was partially contributed by higher proportion
5 with unknown stage when colon cancer diagnosed (6.2% versus 14.6%). The frequency of diagnosis
6 at autopsy for colon cancer among people without mental disorder was also significantly lower than
7 cases (1.1% versus 4.4%).³⁵ However, these two studies did not adjust for potential confounders in
8 their analyses, especially for type of cancer.^{15 35} Another study focusing on breast cancer with
9 confounders adjusted found that a history of major depression was associated with a delayed
10 diagnosis of breast cancer representing an almost ten-fold increased risk, but the opposite direction of
11 association was found for phobia.⁴³ Although we should have sufficient statistical power to identify
12 the differences, our null findings for people undergoing assessment and treatment in secondary
13 mental health services made the issue about delayed diagnosis of cancer among people with mental
14 illness still inconclusive. Although potential explanation about specific psychological characteristics
15 of dispositional insensitivity to threat (if the relation really exists) was found to be associated with
16 delayed help seeking for symptoms of rectal cancer,³⁶ further in-depth investigations on the effect of
17 mental disorders to physical healthcare utilisations is needed.

34
35
36
37
38
39
40 On the issue of survival for people with mental disorders after cancer diagnosis, a previous study of a
41 population-based male Swedish cohort with psychiatric admissions before cancer diagnosis by
42 registration found significantly worse survival, especially for those who had had depressive disorders,
43 neurotic and adjustment disorders, and alcohol-related or other substance use disorders.¹⁴ With a
44 similar study design, Kisley *et al.* identified a significantly elevated risk of cancer mortality for
45 people with psychiatric disorder in Canada.³⁸ Advanced analyses exploring the reasons for elevated
46 all-cause mortality following cancer diagnosis were also reported for people with known mental
47 disorders in Western Australia, finding reduced likelihood of surgery after diagnosis of colorectal,

59
60

1
2 breast, and cervical cancers in people with mental disorders and less radiotherapy or chemotherapy
3 receipt.¹⁵ The US linkage between Surveillance, Epidemiology and End Results data and Medicare
4
5 found that receipt of colon cancer treatment (any treatment at all stages or chemotherapy at stage 3
6
7 only) was significantly lower for people with preexisting any mental disorder, mood disorder,
8
9 psychiatric disorder, and dementia.³⁵ Our study provided additional support to the finding that,
10
11 although the stage of diagnosis for cancer of people with mental illness was not more advanced, these
12
13 people were still at higher risk of death comparing to their counterparts without mental illness. The
14
15 underlying reasons might differ by medical care system in countries. Further details about the
16
17 treatment trajectories after cancer diagnosis for people with mental disorder are needed for advanced
18
19 studies.
20
21
22
23
24
25
26
27

28 **Implications and direction for future studies**

29
30 The wider question about cancer risk and outcome in people with mental disorders has received
31
32 considerable attention over the years, although studies have principally investigated overall
33
34 cancer-related mortality or cancer incidence. While findings about cancer screening uptake rates
35
36 among people with SMI were inconsistent across and within countries,⁴⁴ one possible reason for
37
38 reasonably consistent raised cancer-related mortality in people with mental disorders but inconsistent
39
40 evidence for raised cancer incidence is that the mortality is explained by delays in presentation rather
41
42 than increased risk. However, we found no evidence that prior mental disorder was associated with
43
44 more advanced stage of cancer at diagnosis, a measure of delay in presentation, which might because
45
46 that, in UK, since 2003, GPs have been incentivised under the guide of Quality and Outcomes
47
48 Framework⁴⁵ to offer regular physical health reviews to people with long-term mental health
49
50 problems, including preventative cancer screening appropriate to age and gender since 2006.
51
52
53
54
55
56
57
58
59
60

1
2
3 Instead, consistent with other findings,^{14 15 35 38} we found an association with worse survival after
4 cancer diagnosis that was not explained by stage at presentation. This suggests that effects of mental
5 disorder on cancer mortality primarily exert themselves after the diagnosis. Causal pathways might
6 include reduced access to medical treatment and care, differing decisions about or tolerance of
7 intensive regimes, and the influence of other health problems or drug effects on survival. Also, there
8 might be differences between cancers on the impact to survival for early diagnosis, but there were
9 insufficient data to analyze such differences among types of cancer. Clearly the components of such
10 disadvantage require further evaluation. A greater understanding is needed of levels of utilisation of
11 healthcare services and potential barriers to this among people with mental illness, including the
12 extent to which this is present across individual cancer diagnoses and to which it is accounted for by
13 the specific symptoms of the mental disorders themselves, by accompanying social disadvantage, or
14 potentially by stigma. Also worthy of further evaluation is the potential impact that mental healthcare
15 could have on improving physical health and other indirect influences of mental disorders on adverse
16 health outcomes.

FUNDING

This research was supported by the Biomedical Research Nucleus data management and informatics facility at South London and Maudsley NHS Foundation Trust, which is funded by the National Institute for Health Research (NIHR) Mental Health Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London and a joint infrastructure grant from Guy's and St Thomas' Charity and the Maudsley Charity. CKC, RH, MB, MH, AF, and RS are part-funded by the National Institute for Health Research (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London. The Thames Cancer Registry, King's College London, receives funding from the Department of Health.

CONTRIBUTORSHIP

Everyone listed as an author fulfils all three of the ICMJE guidelines for authorship, including 1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; 2) drafting the article or revising it critically for important intellectual content; and 3) final approval of the version to be published.

DATA SHARING

We declare that we are willing to share our data for the purpose of collaborations to investigators in related academic fields.

ABSTRACT

Background: There have been inconsistent research results reported for the effects of prior serious mental disorders on cancer mortality and morbidity.

Methods: Using the anonymised linkage between a regional monopoly secondary mental health service provider in southeast London and a population-based cancer register, a historical cohort study was constructed. Comparisons between people with and without specific psychiatric diagnosis in the same residence area for risks of advanced stage of cancer at diagnosis and general survival after cancer diagnosed were analysed using logistic and Cox models.

Results: A total of 28,477 cancer cases aged 15+ years old with stage of cancer recorded at diagnosis were identified. Among these, 2,206 subjects had been previously assessed or treated in secondary mental healthcare before their cancer diagnosis and 125 for severe mental illness (schizophrenia, schizoaffective, or bipolar disorders). No associations were found between specific mental disorder diagnoses and beyond-local spread of cancer at presentation. However, people with severe mental disorders, depression, dementia, and substance use disorders had significantly worse survival after cancer diagnosis, independent of cancer stage at diagnosis and other potential confounders.

Conclusions: Previous findings of associations between mental disorders and cancer mortality are more likely to be accounted for by differences in survival after cancer diagnosis rather than by delayed diagnosis.

Strengths and limitations of this study:

Main strengths:

- Longitudinal study design with a data linkage between two case register systems in London, UK
- Mortality information was retrieved from the national registry of death certificates in UK.

Limitations:

- The completeness rate of cancer stage was about 65%, which is within the range reported by other cancer registries in England and did not differ for most of the mental disorder groups of research interest compared to the remaining population.
- Lack of lifestyle factors (smoking, drinking, diet, obesity, and physical activities) for confounding control in survival analysis
- Small cancer case numbers of some specific mental disorders did not permit restricting the sample for sensitivity analyses. Also, size of the linked sample also did not allow further analyses of individual cancer diagnoses.

INTRODUCTION

Numerous studies have indicated a higher risk of all-cause mortality and shorter life expectancy for people with severe mental illness (SMI), including schizophrenia, bipolar disorder, schzoaffective disorder, and sometimes depressive disorders.¹⁻⁸ The profile of causes of death among people with SMI is not substantially different from that in general population, although some specific patterns of death have been suggested, differing by sex, age group, and mental disorder diagnosis.^{3 5-7 9-13} In recent decades, cardiovascular disease, stroke, respiratory diseases, suicide, and cancer have remained the leading causes.^{3 5-7 9-13}

A recent population-based study revealed that men with psychiatric admissions before cancer registration had a significantly worse survival, especially for those with depressive disorders, neurotic and adjustment disorders, and alcohol-related or other substance use disorders.¹⁴ Results from three population-based cohort studies showed significantly increased cancer mortality among people with schizophrenia for both genders,^{5 9 15} but some other studies reported that it occurred in men^{7 13 16 17} or women only.¹⁸ However, other studies found no association with cancer mortality for SMI as a whole or schizophrenia specifically^{7 13 16 17} and even a reduced risk was reported in one study.⁶ Depression has also been found to be associated with an increase in cancer mortality.¹⁹ Studies of the incidence of cancer in people with SMI have principally focused on schizophrenia with varying results, including reduced total cancer incidence,^{18 20-25} no difference,²⁶⁻²⁹ or increased risk.³⁰ A meta-analysis pooling eight studies concluded no association between schizophrenia and incidence of cancer.²⁷ A history of depression or alcohol-related or substance use disorders has been associated with increased cancer,³¹ but inconsistent findings have been found for bipolar disorder,^{32 33} dementia,^{15 18 34} and null for schzoaffective disorder.²⁹ Evidence on the role of mental disease as a comorbidity factor in cancer is therefore still far from conclusive, but tends to indicate cancer

10
11 Thinking of how to solve the puzzle shown on conflicting research results and effects of mental
12 disorders to cancer prognosis, there are two key research questions to be answered. First, to what
13 extent might the reduced recognition of early cancer symptoms in people with mental disorders
14 influence the stage of cancer at diagnosis?^{33 35-37} And, secondly, what is the role of mental disorders
15 on mortality after cancer diagnosis if the issue of later presentation of cancer could be ruled out?
16 Then, an influence of mental disorders on cancer mortality in the absence of a clear effect on
17 underlying risk could be explained by differences in treatment access, response and adherence, as
18 previously raised by Kisely and colleagues.^{15 38} Utilising a data linkage between a large secondary
19 mental healthcare case register in southeast London and the regional cancer registry, we sought to
20 investigate associations between mental disorder and both disease stage at cancer diagnosis and
21 subsequent survival.

33 34 **MATERIALS AND METHODS**

35 36 **The South London and Maudsley NHS Foundation Trust (SLAM) Biomedical Research Centre** 37 38 **(BRC) Case Register**

39
40 The SLAM BRC Case Register was used to provide data on mental disorders for the current study.
41 SLAM is the near-monopoly provider of comprehensive secondary mental health services for a
42 geographic catchment consisting of four London boroughs (Southwark, Lambeth, Lewisham, and
43 Croydon) with approximately 1.23 million residents. Clients' records for all the services provided by
44 SLAM were electronised in 2006. In 2008, the Clinical Record Interactive Search (CRIS) system was
45 developed as a platform for investigators to search and access full but anonymised clinical data from
46 the fully electronic health records system in SLAM for research purposes. All people receiving

9 SLAM care for psychiatric assessments and / or treatment were included in the database. The
10 demographic characteristics and clinical profiles of the Case Register population have been fully
11 described elsewhere.³⁹ Ethical approval as an anonymised data resource for secondary analyses was
12 received from Oxfordshire REC C in 2008 (reference number 08/H0606/71).
13
14

15 16 17 18 **Thames Cancer Registry (TCR)**

19 At the time of the study, TCR was the largest of eight population-based cancer registries in England,
20 covering a population of 12 million residents in London, Kent, Surry, and Sussex. Registration was
21 initiated by pathology reports and clinical records from hospitals and information on death
22 certificates received from the NHS Central Register through the Office of National Statistics in 1999.
23
24 When cancer is recorded as the main or contributing cause of death in the Part 1 section, the
25 certificate is routinely sent to the regional cancer registry. Further information on demographic,
26 clinical details, and treatments received within the first six months after cancer diagnosis was
27 retrieved from hospitals or hospital databases by trained data collection officers. A central regional
28 database was maintained with data added continuously and robust data quality controls. To avoid
29 double counting, information about new tumors was cross-checked against existing registered cases.
30
31 Cancer registration and cancer surveillance take place in English registries under provisions of
32 Section 251 of the Health and Social Care Act and this permission is reviewed annually. The Thames
33 Cancer Registry was assessed to be more than 95% complete in 2001-2007 and considered as of
34 sufficient quality for cancer outcomes analyses.^{40 41}

44
45

46 47 **Anonymised process of data linkage**

48 Data from CRIS and TCR for residents in the SLAM geographic catchment were linked using an
49 anonymisation process by the Health Research Support Service (HRSS) Pilot Programme which was
50
51
52
53
54

operated by the Department of Health as part of the NHS Research Capability Programme in the UK. Memoranda of Understanding were signed between SLAM and TCR through HRSS, which in turn designed and created an infrastructure to provide a safe and confidential platform for health research. With HRSS as the “trusted third party”, the linkage was performed using a series of identifiers including the NHS number and was then irreversibly de-identified, replacing the NHS number with an encrypted HRSS identification (HRSS id). The initial sample selected for analysis comprised individuals on the TCR dataset within SLAM coverage area. Thus, a retrospective cohort study of people under the care of secondary mental health services could be performed.

Covariates included

Mental disorder diagnoses were identified from two sources within CRIS: i) a primary psychiatric diagnosis (Axis 1a) categorised by ICD-10 code (a structured field, compulsory for completion by services, with a specific date in the electronic clinical records system); and ii) a supplementary natural language processing application developed using General Architecture for Text Engineering (GATE) software which extracts text strings relating to a diagnosis statement in correspondence fields. The first diagnoses from either or both sources were then categorised into the following groupings (ICD codes): dementia (F00-03), substance use disorders (F10-19), schizophrenia (F20), schizoaffective disorder (F25), bipolar disorder (F31), depressive disorders (F32-33), anxiety disorders (F40-42), and personality disorders (F60-61). Severe mental illness (SMI) was defined as a diagnosis of schizophrenia (F20), schizoaffective disorder (F25), or bipolar disorder (F31). In the TCR data, tumor stage at presentation of cancer was routinely extracted from an individual’s medical records and categorised as follows: “local” (stage 1), “extension beyond the organ of origin” (stage 2), “regional lymph node involvement” (stage 3), and “metastasis” (stage 4). Cases without sufficient information about disease stage were classified as “not known”. Date of cancer diagnosis, date of

1
2
3
4
5
6
7
8
9 birth, sex, type of cancer, primary care trust (geographic area), and ethnic group were also routinely
10 collected in TCR and were used as covariates. In addition, the income domain of the index of
11 multiple deprivations in 2007 was derived on the basis of the residential postcode.⁴²
12
13

14 15 16 **Statistical analysis**

17
18 All the cancer cases diagnosed in the period from 1999 to 2008 in residents of the catchment area of
19 four London boroughs under SLAM service coverage were included in current analyses. Through the
20 linkage performed by HRSS, any cancer detected after a contact with SLAM was marked. If multiple
21 tumors were registered in one person, only the first cancer onset was considered. Their primary
22 psychiatric diagnosis given in SLAM services before the cancer was identified (if any) as the major
23 exposure of interest in current analyses. Stage of disease at cancer diagnosis was categorised into two
24 groups: i) early stage with no spread or only local extension beyond the organ of origin (localized
25 stage), and ii) late stages with regional lymph node involvement or metastasis (advanced stage). This
26 was treated as a binary dependent variable and was modeled against mental disorder diagnoses by
27 logistic regressions. Cox regression models were then assembled to estimate associations between
28 mental disorder and survival after cancer diagnosis. The duration of follow up was defined as the
29 period from cancer diagnosis to the date of death (any cause) or the end of the follow-up period (12
30 Jun, 2010), provided by TCR. Age at cancer diagnosis, gender, type of cancer, year of cancer
31 diagnosis, primary care trust (geographic area), ethnic groups, deprivation score for income, and
32 stage at cancer diagnosis were treated as potential confounders, where appropriate. Area-level
33 deprivation score for income was classified into quintiles, with the 1st quintile representing the most
34 affluent areas and applied as the reference group in modeling. Stata/IC 12.1 software for Windows
35 (Stata Corporation, 2011) was used for all the analyses.

RESULTS

The study sample

A total of 43,746 cancer cases were identified from TCR records. Among them, 15,166 subjects (34.7%) had no information about their stage of cancer at diagnosis. No significant associations were found between psychiatric diagnosis and missing cancer stage data apart from a higher proportion of missing data in people with dementia (46.8%) compared to the remainder (35.0%). After the exclusion of people without confirmed cancer stage information and those younger than 15 years old at cancer diagnosis (n = 101), with missing date of birth (n = 1) or date of cancer diagnosis (n = 1), 28,477 cases (65.1%) remained and were included in our analyses. Among them, 55.3% were female. Up to the end of 2008, a total of 2,206 of these cancer cases had received any SLAM service (i.e. were present on the CRIS database), and 125 of these had received an SMI diagnosis prior to their cancer diagnosis.

Factors associated with extent of disease at cancer diagnosis

Of the analysed sample of cancer cases, 64.2% (n = 18,290) were diagnosed with localized stage of disease. Descriptive characteristics of the sample by stage at cancer diagnosis are presented in Table 1. Subjects with advanced stage of cancer at diagnosis were older and more likely to be male (both p values < .001), and there was significant variation by cancer type, year of diagnosis, primary care trust, and ethnic group (all p values < .001), although no clear linear trend for socio-economic deprivation was evident (details not shown).

Mental disorder and stage at cancer diagnosis

Associations between preceding mental disorders and stage at cancer diagnosis are summarised in Table 2. In summary, findings were null and there was no evidence of an association with any

12

13 14 **Mental disorder and survival after cancer diagnosis**

15
16 Associations between mental disorders and survival after cancer diagnosis are summarised in Table 3.
17
18 SMI as a whole (and schizophrenia and schizoaffective disorder individually), depression, dementia,
19
20 and substance use disorders were associated with worse survival after cancer diagnosis in fully
21
22 adjusted models with relatively little attenuation following adjustment for stage at cancer diagnosis.
23
24

25 **DISCUSSION**

26 27 **Main findings**

28
29 This linkage between a population-based cancer register and a near-monopoly secondary mental
30
31 health service provider with a geographic catchment of approximately 1.23 million residents
32
33 provided a sufficiently large sample for this investigation. The key findings were that people who had
34
35 been diagnosed with specific mental disorders in the secondary mental health service were not more
36
37 likely to have cancer with advanced stage at diagnosis, but that many of the mental disorder groups
38
39 had worse subsequent survival. This latter finding was significant for SMI as a whole, and for
40
41 schizophrenia and schizoaffective disorder individually, as well as for those with diagnoses of
42
43 depression, dementia, and substance use disorders prior to the cancer diagnosis. The stage of cancer
44
45 at diagnosis in people with mental disorders did not explain their worse subsequent survival.
46
47

48 **Advantages and limitations**

49
50 The study described here benefited from the large size of the two data sources. The linkage allowed
51
52 the longitudinal observation of a substantial number of cases with mental disorder diagnoses who had
53
54

1
2
3
4
5
6
7
8
9 subsequently developed cancer, and comparison group of the remaining people with cancer diagnoses
10 from the same geographic catchment area. Ascertainment of vital status and deaths were achieved by
11 linkage to death certificates provided electronically from the Office for National Statistics.

12
13
14 Limitations include a fairly large proportion with missing data on cancer stage (34.7%). This
15 completeness level is within the range reported by other English registries and represents the data
16 available to the registration process. These levels have been improving with the receipt of electronic
17 pathology data from hospitals. Importantly, the proportions with missing stage data did not differ for
18 most of the mental disorder groups of primary interest compared to the remaining population (the
19 only exception being dementia) and principal findings are therefore unlikely to have been biased by
20 availability of stage information. The other issue was the lack of lifestyle factors for smoking,
21 drinking, diet, obesity, and physical activities in our dataset, which made further confounding control
22 inapplicable. Another limitation was that some of the required data on mental disorders were drawn
23 from years when there was less than full information, since electronic records became comprehensive
24 across all SLAM services during 2006; however, case numbers did not permit restricting the sample
25 any further for sensitivity analyses. The size of the linked sample also did not permit analyses of
26 individual cancer diagnoses. Besides, the significant finding of schizoaffective disorder for survival
27 after cancer diagnosis in Table 3 was based on 5 cases only.

42 **Comparisons with related studies**

43
44 In the relatively scarce literature about potentially delayed cancer diagnoses among people with
45 mental disorders, the most recent published study reported a significantly higher proportion of
46 metastasis at cancer presentation for psychiatric patients comparing to general population (7.1%
47 versus 6.1%) in Western Australia, especially for the cancer of breast and lung.¹⁵ A US study, linking
48 Surveillance, Epidemiology and End Results data to Medicare, found that people without mental
49
50
51
52
53
54

1
2

6
7
8
9 disorder were slightly more likely to have an earlier detection of colon cancer than people who had
10 any mental disorder (53.3% versus 49.7%), although it was partially contributed by higher proportion
11 with unknown stage when colon cancer diagnosed (6.2% versus 14.6%). The frequency of diagnosis
12 at autopsy for colon cancer among people without mental disorder was also significantly lower than
13 cases (1.1% versus 4.4%).³⁵ However, these two studies did not adjust for potential confounders in
14 their analyses, especially for type of cancer.^{15 35} Another study focusing on breast cancer with
15 confounders adjusted found that a history of major depression was associated with a delayed
16 diagnosis of breast cancer representing an almost ten-fold increased risk, but the opposite direction of
17 association was found for phobia.⁴³ Although we should have sufficient statistical power to identify
18 the differences, our null findings for people undergoing assessment and treatment in secondary
19 mental health services made the issue about delayed diagnosis of cancer among people with mental
20 illness still inconclusive. Although potential explanation about specific psychological characteristics
21 of dispositional insensitivity to threat (if the relation really exists) was found to be associated with
22 delayed help seeking for symptoms of rectal cancer,³⁶ further in-depth investigations on the effect of
23 mental disorders to physical healthcare utilisations is needed.

37

38 On the issue of survival for people with mental disorders after cancer diagnosis, a previous study of a
39 population-based male Swedish cohort with psychiatric admissions before cancer diagnosis by
40 registration found significantly worse survival, especially for those who had had depressive disorders,
41 neurotic and adjustment disorders, and alcohol-related or other substance use disorders.¹⁴ With a
42 similar study design, Kiskey *et al.* identified a significantly elevated risk of cancer mortality for
43 people with psychiatric disorder in Canada.³⁸ Advanced analyses exploring the reasons for elevated
44 all-cause mortality following cancer diagnosis were also reported for people with known mental
45 disorders in Western Australia, finding reduced likelihood of surgery after diagnosis of colorectal,

9 breast, and cervical cancers in people with mental disorders and less radiotherapy or chemotherapy
10 receipt.¹⁵ The US linkage between Surveillance, Epidemiology and End Results data and Medicare
11 found that receipt of colon cancer treatment (any treatment at all stages or chemotherapy at stage 3
12 only) was significantly lower for people with preexisting any mental disorder, mood disorder,
13 psychiatric disorder, and dementia.³⁵ Our study provided additional support to the finding that,
14 although the stage of diagnosis for cancer of people with mental illness was not more advanced, these
15 people were still at higher risk of death comparing to their counterparts without mental illness. The
16 underlying reasons might differ by medical care system in countries. Further details about the
17 treatment trajectories after cancer diagnosis for people with mental disorder are needed for advanced
18 studies.

29 **Implications and direction for future studies**

30
31 The wider question about cancer risk and outcome in people with mental disorders has received
32 considerable attention over the years, although studies have principally investigated overall
33 cancer-related mortality or cancer incidence. While findings about cancer screening uptake rates
34 among people with SMI were inconsistent across and within countries,⁴⁴ one possible reason for
35 reasonably consistent raised cancer-related mortality in people with mental disorders but inconsistent
36 evidence for raised cancer incidence is that the mortality is explained by delays in presentation rather
37 than increased risk. However, we found no evidence that prior mental disorder was associated with
38 more advanced stage of cancer at diagnosis, a measure of delay in presentation, which might be because
39 that, in UK, since 2003, GPs have been incentivised under the guide of Quality and Outcomes
40 Framework⁴⁵ to offer regular physical health reviews to people with long-term mental health
41 problems, including preventative cancer screening appropriate to age and gender since 2006.

8
9 Instead, consistent with other findings,^{14 15 35 38} we found an association with worse survival after
10 cancer diagnosis that was not explained by stage at presentation. This suggests that effects of mental
11 disorder on cancer mortality primarily exert themselves after the diagnosis. Causal pathways might
12 include reduced access to medical treatment and care, differing decisions about or tolerance of
13 intensive regimens, and the influence of other health problems or drug effects on survival. Also, there
14 might be differences between cancers on the impact to survival for early diagnosis, but there were
15 insufficient data to analyze such differences among types of cancer. Clearly the components of such
16 disadvantage require further evaluation. A greater understanding is needed of levels of utilisation of
17 healthcare services and potential barriers to this among people with mental illness, including the
18 extent to which this is present across individual cancer diagnoses and to which it is accounted for by
19 the specific symptoms of the mental disorders themselves, by accompanying social disadvantage, or
20 potentially by stigma. Also worthy of further evaluation is the potential impact that mental healthcare
21 could have on improving physical health and other indirect influences of mental disorders on adverse
22 health outcomes.

Table 1. Descriptive statistics of cancer patients in southeast London by stage at cancer presentation from 1999 to 2008

Variables	Number (%) / Mean \pm SD			p-value ^b
	Subjects with stage at cancer diagnosis			
	All cases (N = 43,454) ^a	Localized stage (n = 18,290)	Advanced stage (n = 10,187)	
Age at cancer diagnosis (yrs)	63.31 \pm 17.96	60.38 \pm 19.15	66.80 \pm 14.29	<0.01*
Gender				
Female	3223,242 (53.49)	10,257 (56.08)	5,490 (53.89)	<0.01*
Male	20,212 (46.51)	8,033 (43.92)	4,697 (46.11)	
Type of cancer				
Lung	5,286 (12.16)	1,724 (9.43)	2,068 (20.30)	
Bladder	1,170 (2.69)	636 (3.48)	111 (1.09)	
Breast	5,943 (13.68)	2,592 (14.17)	1,833 (17.99)	
Skin	2,189 (5.04)	1,548 (8.46)	93 (0.91)	<0.01*
Prostate	4,975 (11.45)	2,657 (14.53)	634 (6.22)	
Corpus Uteri	804 (1.85)	485 (2.65)	121 (1.19)	
Colorectal	3,979 (9.16)	1,441 (7.88)	1,531 (15.03)	
Others	19,108 (43.97)	7,207 (39.40)	3,796 (37.26)	

Ethnicity			
White	26,055 (59.96)	10,766 (58.86)	6,797 (66.72)
Black	5,080 (11.69)	2,293 (12.54)	1,293 (12.69)
East Asian	541 (1.24)	222 (1.21)	135 (1.33)
South Asian	804 (1.85)	258 (1.41)	173 (1.70)
Others/Unknown/mixed	10,974 (25.25)	4,751 (25.98)	1,789 (17.56)
Deprivation score (income)			
1 st quintile	2,465 (5.67)	709 (3.88)	417 (4.09)
2 nd quintile	3,308 (7.61)	1,098 (6.00)	629 (6.17)
3 rd quintile	6,520 (15.00)	2,844 (15.55)	1,355 (13.30)
4 th quintile	14,114 (32.48)	6,130 (33.52)	3,308 (32.47)
5 th quintile	17,047 (39.23)	7,509 (41.06)	4,478 (43.96)
