ABSTRACT (word count 250)

Background: Epidemiological evidence suggests that paracetamol may be a risk factor in the development of asthma and its severity. This is the first randomised placebo-controlled trial of the effect of regular paracetamol on bronchial responsiveness and asthma control in adult asthma.

Methods: In a 12-week randomised, double-blind, placebo-controlled, parallel-group study, 94 adults with mild to moderate asthma received 12 weeks of 1g paracetamol twice daily or placebo twice daily. The primary outcome variable was bronchial hyperresponsiveness, measured as the provocation concentration of methacholine causing a 20% fall in FEV₁ (PC₂₀ MCh), at week 12. Secondary outcome variables included FEV₁, FeNO and ACQ score.

Results: 94 participants received randomised treatment (36 and 58 in the paracetamol and placebo groups respectively); 85 participants completed the study. At 12 weeks the mean (SD) logarithm base two PC₂₀ was 1.07 (2.36) in the control group (N=54) and 0.62 (2.09) in the paracetamol group (N=31). After controlling for baseline PC₂₀, the difference (paracetamol minus placebo) was -0.48 doubling dose (95% CI -1.28 to 0.32), P=0.24. There were no statistically significant differences (paracetamol minus placebo) in log FeNO 0.09 (95% CI -0.097 to 0.27)), FEV₁ (-0.07 L (95% CI -0.15 to 0.01)), or ACQ score (-0.04 (95% CI -0.27 to 0.18)).

Conclusions: There was no significant effect of paracetamol on bronchial responsiveness and asthma control in adults with mild to moderate asthma. However, the study findings are limited by low power and the upper confidence interval limits did not rule out a clinically relevant adverse effect.

STRENGTHS AND WEAKNESSES

- Randomised placebo-controlled trial
- Physiological, clinical and immunological outcome measures
- Powered to detect a marked effect on BHR

KEY MESSAGES

What is the key question?

Does regular paracetamol use result in worsening asthma severity?

What is the bottom line?

Paracetamol use did not cause a marked increase in bronchial hyperresponsiveness or asthma control in adult asthma, although it was not possible to rule out a clinically relevant effect.

Why read on?

This is the first randomised placebo-controlled trial to measure the effects of paracetamol in stable adult asthma. The study findings provide information on which the design of further studies can be based.

INTRODUCTION

There is a growing body of evidence to suggest that paracetamol may play an important role as a risk factor for the development of asthma, and that increasing world-wide use may have contributed to the increasing global prevalence of asthma seen over the last 40 years.[1,2]

Childhood asthma risk increases in the offspring of women who consume paracetamol during pregnancy,[3] and paracetamol use in the first 12 months of life is associated with an increased risk of wheezing at 3 years [4,5] and 6-7 years.[6] Cross-sectional surveys in children,[6] adolescents [7] and adults [8-11] consistently demonstrate an association between current paracetamol use and asthma in populations with widely differing lifestyles, standards of living, medical practice and availability of paracetamol. However, there is also evidence that these associations may, in part, be due to confounding by indication in some,[12-14] but not all cohort studies in childhood.[15] Cohort studies in adults have demonstrated that increasing frequency of paracetamol use is positively associated with newly-diagnosed (adult-onset) asthma.[16,17]

There is also evidence that paracetamol may increase the severity of asthma in those with the disease. This primarily comes from the only randomised controlled trial of the effect of paracetamol use for fever and asthma outcomes, in which asthmatic children experiencing a current febrile illness were randomised to receive either paracetamol or ibuprofen.[18] The children who received paracetamol were more likely to require an outpatient visit for asthma compared to children in the ibuprofen group. The increased risk with paracetamol was dose dependent and related to respiratory febrile illnesses rather than other causes of fever. In a case-control study which reported a dose-dependent association between paracetamol use and asthma, a progressively greater risk in those with more severe disease was noted, suggesting an effect on both causation and severity of the disease.[10]

The mounting epidemiological evidence, supported by several biologically plausible mechanisms [19-28] has led to repeated calls [2,5-7,13,29-32] for randomised controlled trials to be undertaken

1 to explore the relationship between paracetamol and asthma. This study is the first randomised
2 controlled trial undertaken to investigate the effect of regular daily paracetamol on asthma severity
3 in adult patients with asthma. It was powered to detect a one doubling dose change in PC₂₀
4 methacholine bronchial hyperresponsiveness (BHR). Markers of airways inflammation and
5 systemic immunological responses were monitored to provide insight into possible mechanisms of
6 action. The hypothesis was that regular paracetamol use would result in a worsening in BHR and
7 asthma control.

METHODS

The study design was a double-blind, randomised, placebo-controlled, parallel group trial based in Wellington, New Zealand. The study methods are summarised with additional details provided in the supplementary appendix. The study was approved by the Central Regional Ethics Committee (CEN/08/12/070) and all participants gave written informed consent. The trial was registered on the Australian New Zealand Clinical Trials Registry (ACTRN12609000551291).

Participants

Participants were identified from the Medical Research Institute of New Zealand (MRINZ) asthma register, general practitioner patient databases, and the general public through advertising. Inclusion criteria included age between 18 and 65 years, wheeze in the previous 12 months and a doctor's diagnosis of asthma, forced expiratory volume in 1 second (FEV₁) \geq 70% predicted at screening and baseline and a PC₂₀ MCh (the provocation concentration of methacholine causing a 20% reduction in FEV₁) of between 0.125 and 16 mg/ml at baseline. Exclusion criteria included regular use of theophylline, ipratropium bromide, tiotropium or leukotriene receptor antagonists in the previous 3 months, alanine aminotransferase (ALT) levels greater than 1.5 times the upper limit of normal at baseline, a history of liver disease or the current use of hepatotoxic drugs, an exacerbation of asthma within the previous two months requiring prednisone or nebulised bronchodilator, current or past cigarette smoking >10 pack years, history of sensitivity or allergy to paracetamol or current regular use of paracetamol, use of high-dose aspirin or non-steroidal anti-inflammatory drugs, history of alcoholism or current excessive alcohol intake, history of previous intentional overdose of paracetamol, previous suicide attempt or current unstable depression, body mass index <16 kg/m², pregnant or breast-feeding women or women not using adequate contraception and participants unsuitable for BHR challenge testing in accordance with American Thoracic Society (ATS) criteria.[33]

Interventions

1 Participants were randomised to receive one of two treatment regimens for 12 weeks. The
2 treatments were paracetamol 1g, administered as two 500mg tablets, or placebo administered as
3 two identically appearing tablets, taken twice daily. The paracetamol and placebo tablets were
4 supplied by Aspen Asia Pacific Ltd, Sydney, Australia.
5
6
7
8
9

10 11 **Randomisation**

12 A computer-generated randomisation schedule was generated by the study statistician and was
13 administered by the study pharmacists. It was necessary to randomise the participants prior to
14 their final eligibility screening visit (visit 2) to enable the study pharmacists adequate time to
15 prepare the study medication for dispensing at visit 2 following final determination of eligibility. If a
16 participant failed one of the eligibility criteria at visit 2, the randomised medication was not
17 dispensed and the participant was withdrawn from the study. The randomisation code was not re-
18 used.

27

28 29 **Blinding**

30 Study investigators, participants, and participant health care providers were blinded through
31 provision of medication as identically appearing tablets in bottles, with neither the investigator
32 dispensing the medication or the participants aware of the allocated treatment.
33

35
36
37
38
39

40 41 **Design**

42 The trial involved four study clinic visits and between two and four additional blood tests over 13
43 weeks (Figure 1). A screening visit (visit 1) was held approximately one week prior to baseline and
44 consisted of a medical history and brief physical examination, pregnancy test where applicable,
45 bronchodilator reversibility testing, liver function screen and allergy skin prick tests (see online
46 supplement for details). A diary was used to record morning and evening peak expiratory flow
47 (PEF) values (prior to asthma medication use) for one week prior to the second visit. Participants
48 who met initial eligibility criteria were randomised at this stage, prior to final eligibility assessment
49 at visit 2.

3
4 At visit 2, designated the baseline visit, the Qoltech asthma control questionnaire (ACQ)[34] was
5 administered and PEF_{var} (PEF variability measured as the amplitude as a percentage of the mean)
6 calculated. Baseline assessments of FEV_1 were undertaken using a Micro Medical Microlab
7 spirometer (Micro Medical, Kent, UK) and Fractional exhaled Nitric Oxide (FeNO) was assessed
8 using a NiOX Flex chemiluminescence analyser (Aerocrine AB, Stockholm, Sweden).

9
10 Methacholine (Methapharm, Ontario, Canada) challenge testing was undertaken via the two-
11 minute tidal breathing dosing protocol recommended by the ATS,[33] as outlined in the online
12 supplement. Participants who met all the eligibility criteria were then dispensed a six-week supply
13 of randomised medication, a medication diary to record administered doses and a prescription for
14 codeine phosphate for emergency pain relief during the trial period. These participants then
15 underwent blood tests including full blood count (eosinophils), total serum immunoglobulin E (IgE),
16 and serum cytokine levels (interferon (IFN)- γ , interleukin (IL)-4, IL-5, IL-13) (see online supplement
17 for details).

32 At visits 3 and 4, six and 12 weeks after baseline, FEV_1 , ACQ, FeNO and blood tests were
33 repeated and medication compliance checked via pill count and medication diary check (see online
34 supplement for details). At the third visit, participants were given a further six-week supply of study
35 medication, a second medication diary, and a diary to record morning and evening PEF values in
36 the final intervention week. At the fourth and final visit, BHR testing was repeated. Liver function
37 tests were monitored throughout the study (see online supplement for details).

47 Outcomes

48 The primary outcome variable was PC_{20} MCh at 12 weeks, adjusted for baseline. Secondary
49 outcome measures were FEV_1 , FEV_1 % predicted, ACQ score and FeNO at six and 12 weeks, and
50 the mean morning peak flow, PEF_{var} , and exacerbations of asthma (requiring a doctor's visit and
51 need for prednisone or nebulised bronchodilator) at 12 weeks. Blood eosinophil, serum IgE, and
52 serum cytokine (IFN- γ , IL-4, IL-5 and IL-13) levels were measured at six and 12 weeks.

Statistical Methods

The primary analysis method was ANCOVA. The logarithm base two PC₂₀ for methacholine at 12 weeks was the primary response variable, with the baseline logarithm base two PC₂₀ as a covariate, and a categorical variable for the paracetamol group. The difference in logarithm base two PC₂₀ was the doubling dose difference between the two randomised groups. Secondary outcome variables, including FEV₁, FEV₁ % predicted, ACQ score, FeNO, mean morning peak flow and PEF_{var} were also analyzed by ANCOVA. The distribution of FeNO, serum IgE and eosinophil count was skewed and normality assumptions for these variables were best met on the natural logarithm scale.

A risk difference and appropriate confidence intervals were calculated for the categorical variable, the number of participants with at least one asthma exacerbation. Simple t-tests were used to compare mean values for ALT, the logarithm transformed FeNO, eosinophil count and IgE by paracetamol or placebo group, as the latter three had skewed distributions. For those variables with a logarithm transformation, the exponent of the difference in logarithms was interpreted as the ratio of mean values.

The analysis was by intention to treat of randomised participants who passed the final eligibility screening and as a result received randomised treatment. No randomised participants who failed the final eligibility screen received randomised treatment or underwent any outcome assessments. For each individual analysis, a two-sided P value of 0.05 was used, with 95% confidence intervals for each estimate. We have not adjusted for multiple statistical testing.

Sample Size

A sample size of 60 in each group has 80% power at the 5% level of significance to detect a difference of one doubling dose in PC₂₀ MCh between the groups, based on a standard deviation of 1.9.[35] To allow for the possibility of up to 10% of study participants withdrawing early from the study, a recruitment target of 66 participants was set for each group.

For peer review only

RESULTS

Recruitment commenced in June 2009 and ended in September 2011. The planned study period of two years was extended by three months due to difficulties in recruitment. Figure 2 shows the flow of participants. There were 724 patients assessed for eligibility at phone screening and/or visit 1; of these, 338 failed to meet the inclusion criteria and 205 declined to participate (see online supplement). There were 181 participants randomised prior to visit 2 based on initial eligibility at visit 1; 91 to the paracetamol group and 92 to the placebo group. 53/91 participants allocated to the paracetamol group and 34/92 allocated to the placebo group were withdrawn at visit 2 as they either did not meet the inclusion/exclusion criteria ($PC_{20} > 16\text{mg/ml}$, $n=68$; $PC_{20} < 0.125\text{mg/ml}$, $n=3$; $FEV_1 < 70\%$ predicted, $n=6$; unable to perform spirometry, $n=1$) or were lost to follow-up or withdrew consent ($n=9$). No study medication was dispensed to the participants who were withdrawn at visit 2 (see online supplement).

Medication was dispensed to 94 participants who commenced the intervention phase following visit 2: 36 randomised to paracetamol and 58 to placebo. The characteristics of the subjects are shown in Table 1. The mean age of participants was 40 years and there were 59 female participants. Approximately 30% of study participants were prescribed inhaled corticosteroids and 18% prescribed long-acting beta agonist drugs. Around 90% of participants had positive skin prick tests to either cat, mixed grass or house dust mite. Participants had mild to moderate asthma, with a baseline ACQ score of 0.86 (SD 0.59). The baseline mean FeNO was 48.9 ppb (SD 41.3) and the mean FEV_1 was 94% of predicted (SD 12.0). The baseline mean PC_{20} was 4.29 mg/ml (SD 4.54).

There were 85/94 participants who completed the study. Five participants were withdrawn from the paracetamol group; two withdrew at the participant's own discretion, one was excluded due to a raised ALT (119 IU/L), one was lost to follow-up and one was excluded due to intercurrent illness. Four participants were withdrawn from the placebo group; two were excluded due to a raised ALT

(207 and 227 IU/L respectively), one withdrew at the participant's own discretion and one was lost to follow-up.

Primary Outcome Variable

At 12 weeks the mean (SD) logarithm base two PC₂₀ was 1.07 (2.36) in the control group (N=54) and 0.62 (2.09) in the paracetamol group (N=31). After controlling for baseline PC₂₀, the difference (expressed as a doubling dose difference, paracetamol minus placebo) was not statistically significant: -0.48 (95% CI -1.28 to 0.32), P=0.24 (Table 2).

Secondary Outcome Variables

There were no statistically significant differences in FEV₁, FEV₁ % predicted, ACQ score, mean morning peak flow or PEF_{var} between the control and paracetamol groups at Week 12 (Table 2) or in FEV₁ or ACQ score at Week 6 (Online Supplement). There were three asthma exacerbations in the placebo group and none in the paracetamol group, an absolute difference of 5.6% (95% CI -0.5 to 11.7%). There was 93.2% compliance in the control group and 90.8% compliance in the paracetamol group when assessed by pill count and medication diaries, a difference of 2.4%, (95% CI -1.0 to 5.8). Serum paracetamol levels (greater than the 30 µmol/L threshold) were detectable in between 31.3 to 38.7% of participants in the paracetamol group and were undetectable in all participants in the placebo group between week 2 and week 12 of the study.

There were no statistically significant differences observed in log FeNO at Week 6 (see Online Supplement), or at Week 12, or in log eosinophil or log IgE levels between the two groups at week 12 (Table 3). Only a proportion of participants had measurable levels of IFN- γ , IL-4, IL-5 and IL-13 at baseline or at other times throughout the trial, precluding meaningful analysis (see online supplement). ALT levels were significantly higher in the paracetamol group, with a mean ALT of 25.4 (SD 9.7) and 19.0 (SD 6.0) in the paracetamol and placebo groups respectively at visit 4, difference 6.3 (95% CI 2.9 to 9.7, p <0.001).

DISCUSSION

This double-blind, randomised, placebo-controlled, parallel group study found no statistically significant reduction in PC₂₀ with 12-weeks paracetamol treatment. However, the results did not rule out a clinically significant effect, with the 95% confidence interval containing the pre-specified difference of one doubling dose reduction in PC₂₀. There were no significant differences observed in any of the pre-specified secondary outcome variables of asthma control, inflammatory or immunological markers.

This is the first reported randomised placebo-controlled trial of the effects of daily paracetamol in stable adult asthma. The only other published randomised controlled trial of paracetamol and asthma was the Boston University Fever Study.[18] Children randomised to the ibuprofen group had a reduced risk of having an outpatient visit for asthma during the 4 week study period (OR 0.56, 95% CI 0.34 to 0.95) compared with children in the paracetamol group. Because the study did not include a placebo treatment, it was not possible to determine whether the observed difference in morbidity according to treatment group was attributable to an increased risk with paracetamol or a decreased risk with ibuprofen.

There are several methodological issues relevant to the interpretation of our study findings. First, as enshrined in the Declaration of Helsinki [36] there is a requirement to study the least vulnerable populations wherever applicable. Most, but not all, of the putative adverse effects of paracetamol on asthma have been shown in observational studies of children and suggest that paracetamol may increase the risk of developing asthma.[1,2] However, as there is some data to suggest that regular paracetamol use may lead to a deterioration in asthma control in adults,[1,10] we opted to firstly examine the effects of paracetamol in adults with stable asthma.

Second, this trial was powered to determine whether there was an effect on BHR of at least one-doubling dose reduction in PC₂₀ MCh. Our ability to achieve the designated sample size completing

1 the study was affected by several factors. First, despite a rigorous recruitment campaign during
2 which over 700 patients were screened, due to the inclusion and exclusion criteria employed to
3 ensure participant safety, only 94 screened participants were dispensed randomised medication.
4
5 Secondly, variability in PC₂₀ from baseline to week 12 was larger than anticipated, with a pooled
6 SD of 2.27 doubling doses compared to that used in the sample size calculation based on a SD of
7 1.9, derived from previous studies.[35] Another factor which affected the study power was the
8 requirement to randomise subjects prior to their final screening visit in order to allow the pharmacy
9 adequate time for dispensing at visit 2, following final determination of eligibility. If the participant
10 failed this final eligibility, the randomised medication was not dispensed, the participant was
11 withdrawn from the study, and the randomisation code was not reused. By chance this resulted in
12 a disparity between the proportion of participants receiving active or placebo study medication.
13
14

15
16 Compliance was high when measured via pill count, and although less than half of participants in
17 the paracetamol group had measurable levels of paracetamol in the blood at the times tested
18 throughout the study, this is likely to be due to the laboratory cut-off for a detectable paracetamol
19 level (30 µmol/L). Following a 1g dose, participant blood levels may fall below this laboratory cut-
20 off level in as little as 3 hours (given an paracetamol half-life of 2 hours and a peak plasma
21 concentration 1 hour after administration of 80 µmol/L [37]).
22
23

24
25 Our 12-week dosing period was chosen based on evidence that regular, long-term use of
26 paracetamol is associated with an increased risk of asthma in adults [9-11,16,17] and that chronic
27 ingestion of therapeutic doses can reduce serum antioxidant capacity in as little as two weeks.[38]
28 We had originally intended to use the maximum daily dose of 4g paracetamol, however chose to
29 administer half this dose due to concerns of liver toxicity. These concerns were based on a
30 previous clinical trial of paracetamol in which the incidence of ALT elevations more than three
31 times the upper limit of normal in healthy participants taking 4g/day for 14 days was 31 to
32 44%.[39] Our results showed no clinically significant liver function derangement with paracetamol
33 administered at a dose of 2g/day for 12 weeks.

54
55
56
57
58
59
60

1
2
3
4 Whilst the study did not demonstrate a statistically significant effect of paracetamol on BHR to
5
6 MCh, the results do not rule out a clinically significant effect, with the upper 95% confidence
7
8 interval of a 1.28 doubling-dose worsening in BHR containing the pre-specified difference of one
9
10 doubling-dose. Furthermore, our point estimate of a reduction in PC₂₀ of 0.48 of a doubling-dose
11
12 could potentially be of major public health significance. As proposed by Mitchell,[40] a small shift to
13
14 the left of the BHR curve in a population could lead to a relatively large increase in the prevalence
15
16 of severe asthma. Relevant to the interpretation of our findings it has recently been calculated that
17
18 a one half doubling dose increase in BHR increases the prevalence of moderate and severe BHR
19
20 by about 30%.[41] Likewise, although the 9% increase in FeNO with paracetamol was not
21
22 statistically significant, a change of this magnitude is considered clinically significant.[42] For
23
24 FEV₁, the point estimate was consistent with a lower value in the paracetamol group, however the
25
26 difference was of uncertain clinical significance and was associated with wide confidence intervals.
27
28
29

30
31 No significant effect was seen on serum IgE or peripheral blood eosinophil levels. It was not
32
33 possible to undertake any meaningful analysis of the cytokine measurements, due to the low
34
35 numbers of participants with detectable levels, and as a result we were unable to determine if
36
37 paracetamol influenced the Th1/Th2 balance. Another less recognised potential mechanism of
38
39 action, which was not directly assessed in this study, relates to neurogenic inflammation of the
40
41 airways through the stimulation of the transient receptor potential ankyrin-1 (TRPA-1) cation
42
43 channel by NAPQI, the metabolite of paracetamol.[26] This pathway, which is activated following
44
45 therapeutic doses of paracetamol, mediates a non-eosinophilic inflammatory response and has
46
47 been implicated in the pathogenesis or provocation of asthma by isocyanates, aldehydes, cigarette
48
49 smoke and chlorine.[43,44]
50
51

52
53 Our findings provide information on which the design of further studies could be based. A trial of
54
55 similar design, utilising the same duration and dose of paracetamol and with BHR testing to MCh
56
57 as the primary outcome variable, based on the standard deviation derived from this study, would

require a sample size of approximately 650 to attain adequate power to detect a difference of 0.5 doubling-doses. Alternatively, a study of short-term use of paracetamol at higher doses could be undertaken, to more closely replicate the common use of paracetamol for relief of fever or pain in self-limited illnesses. Based on our findings, a sample size of 140 would be adequate to determine a 0.5 doubling-dose difference in MCh BHR, and a 10% increase in FeNO, in a short-term study of cross-over design. Finally, our study investigated the effect of paracetamol on asthma severity and not whether paracetamol has a role in the pathogenesis of asthma. Testing this hypothesis would require a clinical trial in infants, which would raise ethical and practical issues regarding consent and the use of placebo for the management of pain or fever in young children. However given the common usage of paracetamol in all age groups including pregnancy and the global burden of asthma, we propose that randomised controlled trials are required to determine the effect of paracetamol use on the development of asthma in infancy and early childhood.

In conclusion, this study has shown no significant effect of 12 weeks of treatment with paracetamol at half the maximum therapeutic daily dose on BHR and asthma control in adults with well controlled asthma. Whilst this outcome provides some reassurance that regular paracetamol use has no marked deleterious effect in adult asthma, further adequately powered studies are needed before the safety of paracetamol for patients with asthma is assured. Furthermore, the study findings do not preclude an effect of paracetamol on the development of asthma in infancy, childhood or adult life.

COMPETING INTERESTS

R Beasley has been a member of the GlaxoSmithKline (NZ) Advisory Board, and received research grants, payment for lectures or support to attend meetings from GlaxoSmithKline, a manufacturer of paracetamol.

FUNDING

S Eysers is a Health Research Council Clinical Research Training Fellow. Funding for the study was through research grants from the Health Research Council of New Zealand, the Wellington Medical Research Foundation, the Asthma and Respiratory Foundation of New Zealand, and the University of Otago.

ADDITIONAL DATA

There are no additional data available.

CONTRIBUTORSHIP STATEMENT:

S Eysers was principal investigator and contributed to study planning, study conduct, data analysis and manuscript preparation. K Perrin contributed to study planning, study conduct and manuscript preparation, M Williams, S Jefferies and M Patel contributed to study conduct, M Weatherall contributed to randomisation, statistical analysis and preparation of manuscript, R Siebers contributed to blood analysis and preparation of manuscript, J Crane contributed to study planning and manuscript preparation, J Travers and P Shirtcliffe were safety investigators and R Beasley contributed to study planning, study conduct, data analysis and manuscript preparation.

³University of Otago Wellington, Wellington, New Zealand

METHODOLOGY

Randomisation

A computer-generated randomisation schedule was generated by the study statistician and was administered by the study pharmacists. It was necessary to randomise the subjects prior to their final eligibility screening visit (visit 2) to enable the study pharmacists adequate time to prepare the study medication for dispensing at visit 2 following final determination of eligibility. Pharmacists received notification from the study investigators that a participant was due to attend visit 2, and assigned the appropriate treatment group to the participant based on the randomisation schedule. Allocated medication was then delivered to the MRINZ research offices in labelled medication bottles, ready for dispensing to study participants at the end of visit 2 if they were eligible for the study. If a participant failed one of the eligibility criteria at visit 2, the randomised medication was not dispensed and the participant was withdrawn from the study. The randomisation code was not re-used.

Skin Prick Testing

Skin prick testing was undertaken to grass (grass mix #7, Hollister Stier Laboratories, USA), house dust mite (*Dermatophagoides pteronyssinus*, Hollister Stier Laboratories, USA), cat pelt (Stallergenes Laboratories, France), and positive (histamine) and negative controls (Hollister Stier Laboratories, USA), performed in accordance with Australasian Society of Clinical Immunology and Allergy (ASCIA) guidelines (Australasian Society of Clinical Immunology and Allergy 2006 (Revised March 2009)).

Methacholine Challenge Testing

Participants were asked to withhold long-acting beta-agonists (LABAs) for 48 hours and short-acting beta-agonists (SABAs) and food or drink containing caffeine for eight hours prior to BHR testing. Methacholine (provocholine) was sourced from Methapharm Inc

(Ontario, Canada) as 1280mg vials, and was diluted with normal saline in a sterile manner, and refrigerated at a concentration of 128mg/ml for a period of up to three months. Methacholine was further diluted for each individual challenge test into doubling concentrations of 0.0125, 0.03, 0.06, 0.125, 0.05, 1, 2, 4, 8, 16, and 32mg/ml and left to warm to room temperature for at least 30 minutes prior to each test. An English Wright nebuliser (Roxon Meditec, Montreal, Canada) was used to deliver the methacholine dose. Basic spirometry was performed prior to challenge testing, and a saline (diluent) dose was given prior to the first methacholine dose. At each inhaled dose, the subject was asked to breath normally through the mouthpiece (with nose clip in place) for two minutes, after which time FEV₁ was measured at 30s and 90s. The next concentration of methacholine was then administered within 5 minutes of the original dose commencement. If FEV₁ fell by $\geq 20\%$ from baseline (or if subject finished all concentrations without a drop in FEV₁), no further medication was given and nebulised salbutamol (5mg/2.5ml) was administered immediately, followed by a 10-minute rest period. The subject was monitored and salbutamol nebuliser repeated if necessary until FEV₁ was within 10% of post-saline baseline. PC20, defined as the provocation concentration of inhaled methacholine required to produce a 20% reduction in FEV₁ was calculated via the formula:

$$\text{Logarithmic PC20} = \text{Antilog} [(20-R1)(\log C2-\log C1)/(R2-R1) + \log C1]$$

where C1 is the methacholine concentration producing less than a 20% Fall in FEV₁ and C2 is that producing a greater than 20% fall in FEV₁. R1 and R2 are the percent FEV₁ reductions produced by C1 and C2 respectively (Cockcroft, Murdock et al. 1983).

Liver Function Tests

Liver function tests included alanine aminotransferase (ALT), alkaline phosphatase (ALP), bilirubin, albumin, total protein and gamma-glutamyl transferase (GGT). Any

1 participant who developed an elevation in ALT of greater than three times the upper limit
2 of normal during the study period was withdrawn from the trial. Blood tests to monitor liver
3 function were undertaken at two and four weeks after randomisation and were
4 accompanied by a phone call to the participant to monitor adverse events. Participants
5 who experienced a rise in ALT two to three times the upper limit of normal during the first
6 six weeks of the study were required to have additional blood tests to monitor liver
7 function eight and 10 weeks after randomisation. In order to maintain investigator
8 blinding, results of liver function tests were kept from the study investigators and viewed
9 only by the allocated safety data reviewers (JT and PS). If further blood tests were
10 required at weeks eight and 10, contact was made with the participant by the safety
11 reviewer directly so as to maintain investigator blinding. If, during the course of the study,
12 any participant was found to have abnormal liver function which required their withdrawal
13 from the study, the safety investigator unblinded the participant in order to inform their
14 ongoing management and notified their health care provider.

34 **Cytokine Measurement**

35 Concentrations of IFN- γ , IL-4, IL-5 and IL-13 were measured by ELISA (Quantikine, R&D
36 Systems, Minneapolis, MN), according to the manufacturer's protocols. The ELISA
37 minimum detectable level for IFN- γ was 12.5 pg/ml, for IL-4 was 27.7 pg/ml, for IL-5 was
38 3.5 pg/ml and for IL-13 was 55.3 pg/ml.

47 **Medication Compliance Monitoring**

48 Compliance with study medication was determined by a review of the medication diary, a
49 count of the units of medication returned at the end of the first and second 6-week study
50 period, and blood paracetamol levels taken at weeks 2, 6 and 12.

51 At visit 3 and 4, participants returned their medication diary and any remaining study
52 medication from the first or second 6-week period of the study. All participants were given
53
54
55
56
57

59
60

1
2 188 tablets of study medication at visit 2 and visit 3, which equated to 6 weeks of fully
3 compliant medication dosing and one extra week in case of a delay in follow-up. The
4 number of days that the participant had been randomised, and therefore the number of
5 doses of study medication expected to have been consumed over that time period were
6 calculated based on the entries in the medication diary. The remaining tablets of study
7 medication were then counted and were compared with the number of tablets expected to
8 be returned.

ABSTRACT (word count 249)

Background: Epidemiological evidence suggests that paracetamol may be a risk factor in the development of asthma and its severity. This is the first randomised placebo-controlled trial of the effect of regular paracetamol on bronchial hyperresponsiveness (BHR) and asthma control in adult asthma.

Methods: In a 12-week randomised, double-blind, placebo-controlled, parallel-group study, 94 adults with mild to moderate asthma received 12 weeks of 1g paracetamol twice daily or placebo twice daily. The primary outcome variable was BHR, measured as provocation concentration of methacholine causing a 20% fall in FEV₁ (PC₂₀), at week 12. Secondary outcome variables included FEV₁, FeNO and ACQ score.

Results: 94 participants received randomised treatment (36 and 58 in paracetamol and placebo groups respectively); 85 participants completed the study. At 12 weeks the mean (SD) logarithm base two PC₂₀ was 1.07 (2.36) in the control group (N=54) and 0.62 (2.09) in the paracetamol group (N=31). After controlling for baseline PC₂₀, the mean difference (paracetamol minus placebo) was -0.48 doubling dose worsening in BHR in the paracetamol group (95% CI -1.28 to 0.32), P=0.24. There were no statistically significant differences (paracetamol minus placebo) in log FeNO 0.09 (95% CI -0.097 to 0.27), FEV₁ (-0.07 L (95% CI -0.15 to 0.01)), or ACQ score (-0.04 (95% CI -0.27 to 0.18)).

Conclusions: There was no significant effect of paracetamol on BHR and asthma control in adults with asthma. However, the study findings are limited by low power and the upper confidence limits did not rule out clinically relevant adverse effects.

STRENGTHS AND WEAKNESSES

- Randomised placebo-controlled trial
- Physiological, clinical and immunological outcome measures
- Powered to detect a marked effect on BHR

KEY MESSAGES

What is the key question?

Does regular paracetamol use result in worsening asthma severity?

What is the bottom line?

Paracetamol use did not cause a marked increase in bronchial hyperresponsiveness or deterioration in asthma control in adults with asthma, although it was not possible to rule out a clinically relevant effect.

Why read on?

This is the first randomised placebo-controlled trial to measure the effects of paracetamol in stable adult asthma. The study findings provide information on which the design of further studies can be based.

INTRODUCTION

There is a growing body of evidence to suggest that paracetamol may play an important role as a risk factor for the development of asthma, and that increasing world-wide use may have contributed to the increasing global prevalence of asthma seen over the last 40 years.[1,2]

Childhood asthma risk increases in the offspring of women who consume paracetamol during pregnancy,[3] and paracetamol use in the first 12 months of life is associated with an increased risk of wheezing at 3 years [4,5] and 6-7 years.[6] Cross-sectional surveys in children,[6] adolescents [7] and adults [8-11] consistently demonstrate an association between current paracetamol use and asthma in populations with widely differing lifestyles, standards of living, medical practice and availability of paracetamol. However, there is also evidence that these associations may, in part, be due to confounding by indication in some,[12-14] but not all cohort studies in childhood.[15] Cohort studies in adults have demonstrated that increasing frequency of paracetamol use is positively associated with newly-diagnosed (adult-onset) asthma.[16,17]

There is also evidence that paracetamol may increase the severity of asthma in those with the disease. This primarily comes from the only randomised controlled trial of the effect of paracetamol use for fever and asthma outcomes, in which asthmatic children experiencing a current febrile illness were randomised to receive either paracetamol or ibuprofen.[18] The children who received paracetamol were more likely to require an outpatient visit for asthma compared to children in the ibuprofen group. The increased risk with paracetamol was dose dependent and related to respiratory febrile illnesses rather than other causes of fever. In a case-control study which reported a dose-dependent association between paracetamol use and asthma, a progressively greater risk in those with more severe disease was noted, suggesting an effect on both causation and severity of the disease.[10]

The mounting epidemiological evidence, supported by several biologically plausible mechanisms [19-28] has led to repeated calls [2,5-7,13,29-32] for randomised controlled trials to be undertaken

1 to explore the relationship between paracetamol and asthma. This study is the first randomised
2 controlled trial undertaken to investigate the effect of regular daily paracetamol on asthma severity
3 in adult patients with asthma. It was powered to detect a one doubling dose change in PC₂₀
4 methacholine bronchial hyperresponsiveness (BHR). Markers of airways inflammation and
5 systemic immunological responses were monitored to provide insight into possible mechanisms of
6 action. The hypothesis was that regular paracetamol use would result in a worsening in BHR and
7 asthma control.

METHODS

The study design was a double-blind, randomised, placebo-controlled, parallel group trial based in Wellington, New Zealand. The study methods are summarised with additional details provided in the supplementary appendix. The study was approved by the Central Regional Ethics Committee (CEN/08/12/070) and all participants gave written informed consent. The trial was registered on the Australian New Zealand Clinical Trials Registry (ACTRN12609000551291).

Participants

Participants were identified from the Medical Research Institute of New Zealand (MRINZ) asthma register, general practitioner patient databases, and the general public through advertising. Inclusion criteria included age between 18 and 65 years, wheeze in the previous 12 months and a doctor's diagnosis of asthma, forced expiratory volume in 1 second (FEV₁) \geq 70% predicted at screening and baseline and a PC₂₀ MCh (the provocation concentration of methacholine causing a 20% reduction in FEV₁) of between 0.125 and 16 mg/ml at baseline. Exclusion criteria included regular use of theophylline, ipratropium bromide, tiotropium or leukotriene receptor antagonists in the previous 3 months, alanine aminotransferase (ALT) levels greater than 1.5 times the upper limit of normal at baseline, a history of liver disease or the current use of hepatotoxic drugs, an exacerbation of asthma within the previous two months requiring prednisone or nebulised bronchodilator, current or past cigarette smoking >10 pack years, history of sensitivity or allergy to paracetamol or current regular use of paracetamol, use of high-dose aspirin or non-steroidal anti-inflammatory drugs, history of alcoholism or current excessive alcohol intake, history of previous intentional overdose of paracetamol, previous suicide attempt or current unstable depression, body mass index <16 kg/m², pregnant or breast-feeding women or women not using adequate contraception and participants unsuitable for BHR challenge testing in accordance with American Thoracic Society (ATS) criteria.[33]

Interventions

Participants were randomised to receive one of two treatment regimens for 12 weeks. The treatments were paracetamol 1g, administered as two 500mg tablets, or placebo administered as two identically appearing tablets, taken twice daily. The paracetamol and placebo tablets were supplied by Aspen Asia Pacific Ltd, Sydney, Australia. All participants were instructed to avoid taking other forms of paracetamol (including over-the-counter remedies containing paracetamol) or non-steroidal anti-inflammatory drugs (NSAIDs) for the duration of the study. All participants were provided with a prescription for codeine to use as an analgesic during the study.

Randomisation

A computer-generated randomisation schedule was generated by the study statistician and was administered by the study pharmacists. It was necessary to randomise the participants prior to their final eligibility screening visit (visit 2) to enable the study pharmacists adequate time to prepare the study medication for dispensing at visit 2 following final determination of eligibility. If a participant failed one of the eligibility criteria at visit 2, the randomised medication was not dispensed and the participant was withdrawn from the study. The randomisation code was not re-used.

Blinding

Study investigators, participants, and participant health care providers were blinded through provision of medication as identically appearing tablets in bottles, with neither the investigator dispensing the medication or the participants aware of the allocated treatment.

Design

The trial involved four study clinic visits and between two and four additional blood tests over 13 weeks (Figure 1). A screening visit (visit 1) was held approximately one week prior to baseline and consisted of a medical history and brief physical examination, pregnancy test where applicable, bronchodilator reversibility testing, liver function screen and allergy skin prick tests (see online

1 supplement for details). A diary was used to record morning and evening peak expiratory flow
2 (PEF) values (prior to asthma medication use) for one week prior to the second visit. Participants
3 who met initial eligibility criteria were randomised at this stage, prior to final eligibility assessment
4 at visit 2.
5
6
7
8
9

10
11 At visit 2, designated the baseline visit, the Qoltech asthma control questionnaire (ACQ)[34] was
12 administered and PEF_{var} (PEF variability measured as the amplitude as a percentage of the mean)
13 calculated. Baseline assessments of FEV_1 were undertaken using a Micro Medical Microlab
14 spirometer (Micro Medical, Kent, UK) and Fractional exhaled Nitric Oxide (FeNO) was assessed
15 using a NiOX Flex chemiluminescence analyser (Aerocrine AB, Stockholm, Sweden).
16 Methacholine (Methapharm, Ontario, Canada) challenge testing was undertaken via the two-
17 minute tidal breathing dosing protocol recommended by the ATS,[33] as outlined in the online
18 supplement. Participants who met all the eligibility criteria were then dispensed a six-week supply
19 of randomised medication, a medication diary to record administered doses and a prescription for
20 codeine phosphate for emergency pain relief during the trial period. These participants then
21 underwent blood tests including full blood count (eosinophils), total serum immunoglobulin E (IgE),
22 and serum cytokine levels (interferon (IFN)- γ , interleukin (IL)-4, IL-5, IL-13) (see online supplement
23 for details).

30
31
32
33
34
35
36
37
38
39

40 At visits 3 and 4, six and 12 weeks after baseline, FEV_1 , ACQ, FeNO and blood tests were
41 repeated and medication compliance checked via pill count and medication diary check (see online
42 supplement for details). At the third visit, participants were given a further six-week supply of study
43 medication, a second medication diary, and a diary to record morning and evening PEF values in
44 the final intervention week. At the fourth and final visit, BHR testing was repeated. Liver function
45 tests were monitored throughout the study (see online supplement for details).

55 Outcomes

56
57
58
59
60

1 The primary outcome variable was PC₂₀ MCh at 12 weeks, adjusted for baseline. This direct
2 measure of BHR was chosen as an objective well standardised physiological measure of asthma
3 severity, recommended for monitoring the effects of therapy which may modify asthma
4 severity.[33,35] Secondary outcome measures were FEV₁, FEV₁ % predicted, ACQ score and
5 FeNO at six and 12 weeks, and the mean morning peak flow, PEF_{var}, and exacerbations of asthma
6 (requiring a doctor's visit and need for prednisone or nebulised bronchodilator) at 12 weeks. Blood
7 eosinophil, serum IgE, and serum cytokine (IFN- γ , IL-4, IL-5 and IL-13) levels were measured at
8 six and 12 weeks.

15
16
17
18
19

20 **Statistical Methods**

21 The primary analysis method was ANCOVA. The logarithm base two PC₂₀ for methacholine at 12
22 weeks was the primary response variable, with the baseline logarithm base two PC₂₀ as a
23 covariate, and a categorical variable for the paracetamol group. The difference in logarithm base
24 two PC₂₀ was the doubling dose difference between the two randomised groups. Secondary
25 outcome variables, including FEV₁, FEV₁ % predicted, ACQ score, FeNO, mean morning peak flow
26 and PEF_{var} were also analyzed by ANCOVA. The distribution of FeNO, serum IgE and eosinophil
27 count was skewed and normality assumptions for these variables were best met on the natural
28 logarithm scale.
29
30
31
32
33
34
35
36
37
38
39

40 The proportion of participants with at least one asthma exacerbation was compared as an absolute
41 risk difference, with an appropriate confidence interval, because in the event there were no asthma
42 exacerbations in one of the randomised groups so that a relative risk could not be calculated.
43
44

45 Simple t-tests were used to compare mean values for ALT by randomised group. FeNO, eosinophil
46 count and IgE were logarithm transformed because of skewed distributions, and the difference in
47 logarithms was compared by a t-test. For those three variables with a logarithm transformation, the
48 exponent of the difference in logarithms is interpreted as the ratio of mean values.
49
50
51
52
53
54
55
56
57
58
59
60

1 The analysis was by intention to treat of randomised participants who passed the final eligibility
2 screening and as a result received randomised treatment. No randomised participants who failed
3 the final eligibility screen received randomised treatment or underwent any outcome assessments.
4
5 For each individual analysis, a two-sided P value of 0.05 was used, with 95% confidence intervals
6
7 for each estimate. We have not adjusted for multiple statistical testing.
8
9
10

11 **Sample Size**

12
13
14 A sample size of 60 in each group has 80% power at the 5% level of significance to detect a difference
15
16 of one doubling dose in PC₂₀ MCh between the groups, based on a standard deviation of 1.9.[36] To
17
18 allow for the possibility of up to 10% of study participants withdrawing early from the study, a recruitment
19
20 target of 66 participants was set for each group.

RESULTS

Recruitment commenced in June 2009 and ended in September 2011. The planned study period of two years was extended by three months due to difficulties in recruitment. Figure 2 shows the flow of participants. There were 724 patients assessed for eligibility at phone screening and/or visit 1; of these, 338 failed to meet the inclusion criteria and 205 declined to participate (see online supplement). There were 181 participants randomised prior to visit 2 based on initial eligibility at visit 1; 91 to the paracetamol group and 92 to the placebo group. 53/91 participants allocated to the paracetamol group and 34/92 allocated to the placebo group were withdrawn at visit 2 as they either did not meet the inclusion/exclusion criteria ($PC_{20} > 16\text{mg/ml}$, $n=68$; $PC_{20} < 0.125\text{mg/ml}$, $n=3$; $FEV_1 < 70\%$ predicted, $n=6$; unable to perform spirometry, $n=1$) or were lost to follow-up or withdrew consent ($n=9$). No study medication was dispensed to the participants who were withdrawn at visit 2 (see online supplement).

Medication was dispensed to 94 participants who commenced the intervention phase following visit 2: 36 randomised to paracetamol and 58 to placebo. The characteristics of the subjects are shown in Table 1. The mean age of participants was 40 years and there were 59 female participants. Approximately 30% of study participants were prescribed inhaled corticosteroids and 18% prescribed long-acting beta agonist drugs. Around 90% of participants had positive skin prick tests to either cat, mixed grass or house dust mite. Participants had mild to moderate asthma, with a baseline ACQ score of 0.86 (SD 0.59). The baseline mean FeNO was 48.9 ppb (SD 41.3) and the mean FEV_1 was 94% of predicted (SD 12.0). The baseline mean PC_{20} was 4.29 mg/ml (SD 4.54).

There were 85/94 participants who completed the study. Five participants were withdrawn from the paracetamol group; two withdrew at the participant's own discretion, one was excluded due to a raised ALT (119 IU/L), one was lost to follow-up and one was excluded due to intercurrent illness. Four participants were withdrawn from the placebo group; two were excluded due to a raised ALT

(207 and 227 IU/L respectively), one withdrew at the participant's own discretion and one was lost to follow-up.

Primary Outcome Variable

At 12 weeks the mean (SD) logarithm base two PC₂₀ was 1.07 (2.36) in the control group (N=54) and 0.62 (2.09) in the paracetamol group (N=31). After controlling for baseline PC₂₀, the difference (expressed as a doubling dose difference, paracetamol minus placebo) was not statistically significant: -0.48 (95% CI -1.28 to 0.32), P=0.24 (Table 2).

Secondary Outcome Variables

There were no statistically significant differences in FEV₁, FEV₁ % predicted, ACQ score, mean morning peak flow or PEF_{var} between the control and paracetamol groups at Week 12 (Table 2) or in FEV₁ or ACQ score at Week 6 (Online Supplement). There were three asthma exacerbations in the placebo group and none in the paracetamol group, an absolute difference of 5.6% (95% CI -0.5 to 11.7%). There was 93.2% compliance in the control group and 90.8% compliance in the paracetamol group when assessed by pill count and medication diaries, a difference of 2.4%, (95% CI -1.0 to 5.8). Serum paracetamol levels (greater than the 30 µmol/L threshold) were detectable in between 31.3 to 38.7% of participants in the paracetamol group and were undetectable in all participants in the placebo group between week 2 and week 12 of the study.

There were no statistically significant differences observed in log FeNO at Week 6 (see Online Supplement), or at Week 12, or in log eosinophil or log IgE levels between the two groups at week 12 (Table 3). Only a proportion of participants had measurable levels of IFN- γ , IL-4, IL-5 and IL-13 at baseline or at other times throughout the trial, precluding meaningful analysis (see online supplement). ALT levels were significantly higher in the paracetamol group, with a mean ALT of 25.4 (SD 9.7) and 19.0 (SD 6.0) in the paracetamol and placebo groups respectively at visit 4, difference 6.3 (95% CI 2.9 to 9.7, p <0.001).

DISCUSSION

This double-blind, randomised, placebo-controlled, parallel group study found no statistically significant increase in BHR with 12-weeks paracetamol treatment. However, the results did not rule out a clinically significant effect, with the 95% confidence interval containing the pre-specified difference of one doubling dose reduction in PC₂₀. There were no significant differences observed in any of the pre-specified secondary outcome variables of asthma control, inflammatory or immunological markers.

This is the first reported randomised placebo-controlled trial of the effects of daily paracetamol in stable adult asthma. The only other published randomised controlled trial of paracetamol and asthma was the Boston University Fever Study.[18] Children randomised to the ibuprofen group had a reduced risk of having an outpatient visit for asthma during the 4 week study period (OR 0.56, 95% CI 0.34 to 0.95) compared with children in the paracetamol group. Because the study did not include a placebo treatment, it was not possible to determine whether the observed difference in morbidity according to treatment group was attributable to an increased risk with paracetamol or a decreased risk with ibuprofen.

There are several methodological issues relevant to the interpretation of our study findings. First, as enshrined in the Declaration of Helsinki [37] there is a requirement to study the least vulnerable populations wherever applicable. Most, but not all, of the putative adverse effects of paracetamol on asthma have been shown in observational studies of children and suggest that paracetamol may increase the risk of developing asthma.[1,2] However, as there is some data to suggest that regular paracetamol use may lead to a deterioration in asthma control in adults,[1,10] we opted to firstly examine the effects of paracetamol in adults with stable asthma.

Second, this trial was powered to determine whether there was an effect on BHR of at least one-doubling dose reduction in PC₂₀ MCh. Our ability to achieve the designated sample size completing

1 the study was affected by several factors. First, despite a rigorous recruitment campaign during
2 which over 700 patients were screened, due to the inclusion and exclusion criteria employed to
3 ensure participant safety, only 94 screened participants were dispensed randomised medication.
4
5 Secondly, variability in PC₂₀ from baseline to week 12 was larger than anticipated, with a pooled
6 SD of 2.27 doubling doses compared to that used in the sample size calculation based on a SD of
7 1.9, derived from previous studies.[36] Another factor which affected the study power was the
8 requirement to randomise subjects prior to their final screening visit in order to allow the pharmacy
9 adequate time for dispensing at visit 2, following final determination of eligibility. If the participant
10 failed this final eligibility, the randomised medication was not dispensed, the participant was
11 withdrawn from the study, and the randomisation code was not reused. By chance this resulted in
12 a disparity between the proportion of participants receiving active or placebo study medication. The
13 power was reduced further due to the withdrawal of 10% of participants following randomisation.
14 As there is an uncertain association between observed variables and missing BHR data in these
15 participants, it was not possible to perform a robust imputation.

32 Compliance was high when measured via pill count, and although less than half of participants in
33 the paracetamol group had measurable levels of paracetamol in the blood at the times tested
34 throughout the study, this is likely to be due to the laboratory cut-off for a detectable paracetamol
35 level (30 µmol/L). Following a 1g dose, participant blood levels may fall below this laboratory cut-
36 off level in as little as 3 hours (given an paracetamol half-life of 2 hours and a peak plasma
37 concentration 1 hour after administration of 80 µmol/L [38]). The use of this laboratory cut-off for
38 paracetamol levels meant that it was not possible to investigate medication compliance through
39 this method.

50

51 Our 12-week dosing period was chosen based on evidence that regular, long-term use of
52 paracetamol is associated with an increased risk of asthma in adults [9-11,16,17] and that chronic
53 ingestion of therapeutic doses can reduce serum antioxidant capacity in as little as two weeks.[39]
54 We had originally intended to use the maximum daily dose of 4g paracetamol, however chose to
55
56
57
58
59
60

1 administer half this dose due to concerns of liver toxicity. These concerns were based on a
2
3 previous clinical trial of paracetamol in which the incidence of ALT elevations more than three
4
5 times the upper limit of normal in healthy participants taking 4g/day for 14 days was 31 to
6
7 44%.[40] Our results showed no clinically significant liver function derangement with paracetamol
8
9 administered at a dose of 2g/day for 12 weeks.
10

11
12
13
14 Whilst the study did not demonstrate a statistically significant effect of paracetamol on BHR to
15
16 MCh, the results do not rule out a clinically significant effect, with the upper 95% confidence
17
18 interval of a 1.28 doubling-dose worsening in BHR containing the pre-specified difference of one
19
20 doubling-dose. Furthermore, our point estimate of a reduction in PC₂₀ of 0.48 of a doubling-dose
21
22 could potentially be of major public health significance. As proposed by Mitchell,[41] a small shift to
23
24 the left of the BHR curve in a population could lead to a relatively large increase in the prevalence
25
26 of severe asthma. Relevant to the interpretation of our findings it has recently been calculated that
27
28 a one half doubling dose increase in BHR increases the prevalence of moderate and severe BHR
29
30 by about 30%.[42] Likewise, although the 9% increase in FeNO with paracetamol was not
31
32 statistically significant, a change of this magnitude is considered clinically significant.[43] For
33
34 FEV₁, the point estimate was consistent with a lower value in the paracetamol group, however the
35
36 difference was of uncertain clinical significance and was associated with wide confidence intervals.
37
38
39

40 No significant effect was seen on serum IgE or peripheral blood eosinophil levels. It was not
41
42 possible to undertake any meaningful analysis of the cytokine measurements, due to the low
43
44 numbers of participants with detectable levels, and as a result we were unable to determine if
45
46 paracetamol influenced the Th1/Th2 balance. Another less recognised potential mechanism of
47
48 action, which was not directly assessed in this study, relates to neurogenic inflammation of the
49
50 airways through the stimulation of the transient receptor potential ankyrin-1 (TRPA-1) cation
51
52 channel by NAPQI, the metabolite of paracetamol.[26] This pathway, which is activated following
53
54 therapeutic doses of paracetamol, mediates a non-eosinophilic inflammatory response and has

been implicated in the pathogenesis or provocation of asthma by isocyanates, aldehydes, cigarette smoke and chlorine.[44,45]

Our findings provide information on which the design of further studies could be based. A trial of similar design, utilising the same duration and dose of paracetamol and with BHR testing to MCh as the primary outcome variable, based on the standard deviation derived from this study, would require a sample size of approximately 650 to attain adequate power to detect a difference of 0.5 doubling-doses. Alternatively, a study of short-term use of paracetamol at higher doses could be undertaken, to more closely replicate the common use of paracetamol for relief of fever or pain in self-limited illnesses. Based on our findings, a sample size of 140 would be adequate to determine a 0.5 doubling-dose difference in MCh BHR, and a 10% increase in FeNO, in a short-term study of cross-over design. Important issues with the design of such a study are the duration of both the treatment periods and the crossover period. It would be important if possible to include a placebo rather than ibuprofen arm, as NSAIDs may have the potential to both cause NSAID-induced bronchospasm, as well as reducing asthma severity with long term use.[29]

Finally, our study investigated the effect of paracetamol on asthma severity and not whether paracetamol has a role in the pathogenesis of asthma. Testing this hypothesis would require clinical trials both of the effect of paracetamol use in pregnancy on the development of asthma in childhood, and the effect of paracetamol use in infants and older children and subsequent asthma risk. Such studies would raise ethical and practical issues regarding consent and the use of placebo for the management of pain or fever during pregnancy and in young children. However given the common usage of paracetamol in all age groups including pregnancy and the global burden of asthma, we propose that randomised controlled trials are required to determine the effect of paracetamol use on the development of asthma in infancy and early childhood.

In conclusion, this study has shown no significant effect of 12 weeks of treatment with paracetamol at half the maximum therapeutic daily dose on BHR and asthma control in adults with well

1 controlled asthma. Whilst this outcome provides some reassurance that regular paracetamol use
2
3 has no marked deleterious effect in adult asthma, further adequately powered studies are needed
4
5 before the safety of paracetamol for patients with asthma is assured. Furthermore, the study
6
7 findings do not preclude an effect of paracetamol on the development of asthma in infancy,
8
9 childhood or adult life.

COMPETING INTERESTS

R Beasley has been a member of the GlaxoSmithKline (NZ) Advisory Board, and received research grants, payment for lectures or support to attend meetings from GlaxoSmithKline, a manufacturer of paracetamol.

FUNDING

SJ Ioannides is a Health Research Council Clinical Research Training Fellow. Funding for the study was through research grants from the Health Research Council of New Zealand, the Wellington Medical Research Foundation, the Asthma and Respiratory Foundation of New Zealand, and the University of Otago.

CONTRIBUTORSHIP STATEMENT:

SJ Ioannides was principal investigator and contributed to study planning, study conduct, data analysis and manuscript preparation. K Perrin contributed to study planning, study conduct and manuscript preparation, M Williams, S Jefferies and M Patel contributed to study conduct, M Weatherall contributed to randomisation, statistical analysis and preparation of manuscript, R Siebers contributed to blood analysis and preparation of manuscript, J Crane contributed to study planning and manuscript preparation, J Travers and P Shirtcliffe were safety investigators and R Beasley contributed to study planning, study conduct, data analysis and manuscript preparation

ABSTRACT (word count 250249)

Background: Epidemiological evidence suggests that paracetamol may be a risk factor in the development of asthma and its severity. This is the first randomised placebo-controlled trial of the effect of regular paracetamol on bronchial hyperresponsiveness (BHR) and asthma control in adult asthma.

Methods: In a 12-week randomised, double-blind, placebo-controlled, parallel-group study, 94 adults with mild to moderate asthma received 12 weeks of 1g paracetamol twice daily or placebo twice daily. The primary outcome variable was bronchial hyperresponsivenessBHR, measured as ~~the~~ provocation concentration of methacholine causing a 20% fall in FEV₁ (PC₂₀MCh), at week 12. Secondary outcome variables included FEV₁, FeNO and ACQ score.

Results: 94 participants received randomised treatment (36 and 58 in ~~the~~ paracetamol and placebo groups respectively); 85 participants completed the study. At 12 weeks the mean (SD) logarithm base two PC₂₀ was 1.07 (2.36) in the control group (N=54) and 0.62 (2.09) in the paracetamol group (N=31). After controlling for baseline PC₂₀, the mean difference (paracetamol minus placebo) was -0.48 doubling dose worsening in BHR in the paracetamol group (95% CI -1.28 to 0.32), P=0.24. There were no statistically significant differences (paracetamol minus placebo) in log FeNO 0.09 (95% CI -0.097 to 0.27)), FEV₁ (-0.07 L (95% CI -0.15 to 0.01)), or ACQ score (-0.04 (95% CI -0.27 to 0.18)).

Conclusions: There was no significant effect of paracetamol on bronchial responsivenessBHR and asthma control in adults with mild to moderate asthma. However, the study findings are limited by low power and the upper confidence interval limits did not rule out a clinically relevant adverse effects.

STRENGTHS AND WEAKNESSES

- Randomised placebo-controlled trial
- Physiological, clinical and immunological outcome measures
- Powered to detect a marked effect on BHR

KEY MESSAGES

What is the key question?

Does regular paracetamol use result in worsening asthma severity?

What is the bottom line?

Paracetamol use did not cause a marked increase in bronchial hyperresponsiveness or [deterioration in](#) asthma control in [adults with](#) asthma, although it was not possible to rule out a clinically relevant effect.

Why read on?

This is the first randomised placebo-controlled trial to measure the effects of paracetamol in stable adult asthma. The study findings provide information on which the design of further studies can be based.

ADDITIONAL DATA

There are no additional data available.

CONTRIBUTORSHIP STATEMENT:

[S-Eyers](#), [J Ioannides](#) was principal investigator and contributed to study planning, study conduct, data analysis and manuscript preparation. INTRODUCTION

There is a growing body of evidence to suggest that paracetamol may play an important role as a risk factor for the development of asthma, and that increasing world-wide use may have contributed to the increasing global prevalence of asthma seen over the last 40 years.[1,2]

Childhood asthma risk increases in the offspring of women who consume paracetamol during pregnancy,[3] and paracetamol use in the first 12 months of life is associated with an increased risk of wheezing at 3 years [4,5] and 6-7 years.[6] Cross-sectional surveys in children,[6] adolescents [7] and adults [8-11] consistently demonstrate an association between current paracetamol use and asthma in populations with widely differing lifestyles, standards of living, medical practice and availability of paracetamol. However, there is also evidence that these associations may, in part, be due to confounding by indication in some,[12-14] but not all cohort studies in childhood.[15] Cohort studies in adults have demonstrated that increasing frequency of paracetamol use is positively associated with newly-diagnosed (adult-onset) asthma.[16,17]

There is also evidence that paracetamol may increase the severity of asthma in those with the disease. This primarily comes from the only randomised controlled trial of the effect of paracetamol use for fever and asthma outcomes, in which asthmatic children experiencing a current febrile illness were randomised to receive either paracetamol or ibuprofen.[18] The children who received paracetamol were more likely to require an outpatient visit for asthma compared to children in the ibuprofen group. The increased risk with paracetamol was dose dependent and related to respiratory febrile illnesses rather than other causes of fever. In a case-control study which reported a dose-dependent association between paracetamol use and asthma, a progressively greater risk in those with more severe disease was noted, suggesting an effect on both causation and severity of the disease.[10]

The mounting epidemiological evidence, supported by several biologically plausible mechanisms [19-28] has led to repeated calls [2,5-7,13,29-32] for randomised controlled trials to be undertaken

1
2
3
4
5
6 to explore the relationship between paracetamol and asthma. This study is the first randomised
7 controlled trial undertaken to investigate the effect of regular daily paracetamol on asthma severity
8 in adult patients with asthma. It was powered to detect a one doubling dose change in PC₂₀
9 methacholine bronchial hyperresponsiveness (BHR). Markers of airways inflammation and
10 systemic immunological responses were monitored to provide insight into possible mechanisms of
11 action. The hypothesis was that regular paracetamol use would result in a worsening in BHR and
12 asthma control.

METHODS

The study design was a double-blind, randomised, placebo-controlled, parallel group trial based in Wellington, New Zealand. The study methods are summarised with additional details provided in the supplementary appendix. The study was approved by the Central Regional Ethics Committee (CEN/08/12/070) and all participants gave written informed consent. The trial was registered on the Australian New Zealand Clinical Trials Registry (ACTRN12609000551291).

Participants

Participants were identified from the Medical Research Institute of New Zealand (MRINZ) asthma register, general practitioner patient databases, and the general public through advertising. Inclusion criteria included age between 18 and 65 years, wheeze in the previous 12 months and a doctor's diagnosis of asthma, forced expiratory volume in 1 second (FEV_1) $\geq 70\%$ predicted at screening and baseline and a PC_{20} MCh (the provocation concentration of methacholine causing a 20% reduction in FEV_1) of between 0.125 and 16 mg/ml at baseline. Exclusion criteria included regular use of theophylline, ipratropium bromide, tiotropium or leukotriene receptor antagonists in the previous 3 months, alanine aminotransferase (ALT) levels greater than 1.5 times the upper limit of normal at baseline, a history of liver disease or the current use of hepatotoxic drugs, an exacerbation of asthma within the previous two months requiring prednisone or nebulised bronchodilator, current or past cigarette smoking >10 pack years, history of sensitivity or allergy to paracetamol or current regular use of paracetamol, use of high-dose aspirin or non-steroidal anti-inflammatory drugs, history of alcoholism or current excessive alcohol intake, history of previous intentional overdose of paracetamol, previous suicide attempt or current unstable depression, body mass index <16 kg/m², pregnant or breast-feeding women or women not using adequate contraception and participants unsuitable for BHR challenge testing in accordance with American Thoracic Society (ATS) criteria.[33]

Interventions

[BMJ Open – RCT paracetamol – [4/10/13/18/12/13](#)]

Page 7

1
2
3
4
5
6 Participants were randomised to receive one of two treatment regimens for 12 weeks. The
7 treatments were paracetamol 1g, administered as two 500mg tablets, or placebo administered as
8 two identically appearing tablets, taken twice daily. The paracetamol and placebo tablets were
9 supplied by Aspen Asia Pacific Ltd, Sydney, Australia. All participants were instructed to avoid
10 taking other forms of paracetamol (including over-the-counter remedies containing paracetamol) or
11 non-steroidal anti-inflammatory drugs (NSAIDs) for the duration of the study. All participants were
12 provided with a prescription for codeine to use as an analgesic during the study.
13
14
15
16
17
18
19

20 Randomisation

21 A computer-generated randomisation schedule was generated by the study statistician and was
22 administered by the study pharmacists. It was necessary to randomise the participants prior to
23 their final eligibility screening visit (visit 2) to enable the study pharmacists adequate time to
24 prepare the study medication for dispensing at visit 2 following final determination of eligibility. If a
25 participant failed one of the eligibility criteria at visit 2, the randomised medication was not
26 dispensed and the participant was withdrawn from the study. The randomisation code was not re-
27 used.
28
29
30
31
32
33
34

35 Blinding

36 Study investigators, participants, and participant health care providers were blinded through
37 provision of medication as identically appearing tablets in bottles, with neither the investigator
38 dispensing the medication or the participants aware of the allocated treatment.
39
40
41
42
43

44 Design

45 The trial involved four study clinic visits and between two and four additional blood tests over 13
46 weeks (Figure 1). A screening visit (visit 1) was held approximately one week prior to baseline and
47 consisted of a medical history and brief physical examination, pregnancy test where applicable,
48 bronchodilator reversibility testing, liver function screen and allergy skin prick tests (see online
49 supplement for details). A diary was used to record morning and evening peak expiratory flow

5
6 (PEF) values (prior to asthma medication use) for one week prior to the second visit. Participants
7 who met initial eligibility criteria were randomised at this stage, prior to final eligibility assessment
8 at visit 2.
9

10
11
12 At visit 2, designated the baseline visit, the Qoltech asthma control questionnaire (ACQ)[34] was
13 administered and PEF_{var} (PEF variability measured as the amplitude as a percentage of the mean)
14 calculated. Baseline assessments of FEV_1 were undertaken using a Micro Medical Microlab
15 spirometer (Micro Medical, Kent, UK) and Fractional exhaled Nitric Oxide (FeNO) was assessed
16 using a NiOX Flex chemiluminescence analyser (Aerocrine AB, Stockholm, Sweden).
17
18 Methacholine (Methapharm, Ontario, Canada) challenge testing was undertaken via the two-
19 minute tidal breathing dosing protocol recommended by the ATS,[33] as outlined in the online
20 supplement. Participants who met all the eligibility criteria were then dispensed a six-week supply
21 of randomised medication, a medication diary to record administered doses and a prescription for
22 codeine phosphate for emergency pain relief during the trial period. These participants then
23 underwent blood tests including full blood count (eosinophils), total serum immunoglobulin E (IgE),
24 and serum cytokine levels (interferon (IFN)- γ , interleukin (IL)-4, IL-5, IL-13) (see online supplement
25 for details).
26
27
28
29
30
31
32
33
34
35
36

37 At visits 3 and 4, six and 12 weeks after baseline, FEV_1 , ACQ, FeNO and blood tests were
38 repeated and medication compliance checked via pill count and medication diary check (see online
39 supplement for details). At the third visit, participants were given a further six-week supply of study
40 medication, a second medication diary, and a diary to record morning and evening PEF values in
41 the final intervention week. At the fourth and final visit, BHR testing was repeated. Liver function
42 tests were monitored throughout the study (see online supplement for details).

49 Outcomes

50
51 The primary outcome variable was PC_{20} MCh at 12 weeks, adjusted for baseline. [This direct](#)
52 [measure of BHR was chosen as an objective well standardised physiological measure of asthma](#)
53
54

severity, recommended for monitoring the effects of therapy which may modify asthma

severity.^[33,35] Secondary outcome measures were FEV₁, FEV₁ % predicted, ACQ score and FeNO at six and 12 weeks, and the mean morning peak flow, PEF_{var}, and exacerbations of asthma (requiring a doctor's visit and need for prednisone or nebulised bronchodilator) at 12 weeks. Blood eosinophil, serum IgE, and serum cytokine (IFN- γ , IL-4, IL-5 and IL-13) levels were measured at six and 12 weeks.

Statistical Methods

The primary analysis method was ANCOVA. The logarithm base two PC₂₀ for methacholine at 12 weeks was the primary response variable, with the baseline logarithm base two PC₂₀ as a covariate, and a categorical variable for the paracetamol group. The difference in logarithm base two PC₂₀ was the doubling dose difference between the two randomised groups. Secondary outcome variables, including FEV₁, FEV₁ % predicted, ACQ score, FeNO, mean morning peak flow and PEF_{var} were also analyzed by ANCOVA. The distribution of FeNO, serum IgE and eosinophil count was skewed and normality assumptions for these variables were best met on the natural logarithm scale.

The proportion of participants with at least one asthma exacerbation was compared as an absolute risk difference, with an appropriate confidence interval, because in the event there were no asthma exacerbations in one of the randomised groups so that a relative risk could not be calculated.

Simple t-tests were used to compare mean values for ALT by randomised group. FeNO, eosinophil count and IgE were logarithm transformed because of skewed distributions, and the difference in logarithms was compared by a t-test. For those three variables with a logarithm transformation, the exponent of the difference in logarithms is interpreted as the ratio of mean values. A risk difference and appropriate confidence intervals were calculated for the categorical variable, the number of participants with at least one asthma exacerbation. Simple t tests were used to compare mean values for ALT, the logarithm transformed FeNO, eosinophil count and IgE by paracetamol or placebo group, as the latter three had skewed distributions. For those variables with a logarithm

10
11 The analysis was by intention to treat of randomised participants who passed the final eligibility
12 screening and as a result received randomised treatment. No randomised participants who failed
13 the final eligibility screen received randomised treatment or underwent any outcome assessments.
14
15 For each individual analysis, a two-sided P value of 0.05 was used, with 95% confidence intervals
16 for each estimate. We have not adjusted for multiple statistical testing.

Sample Size

A sample size of 60 in each group has 80% power at the 5% level of significance to detect a difference of one doubling dose in PC₂₀ MCh between the groups, based on a standard deviation of 1.9.^[3536] To allow for the possibility of up to 10% of study participants withdrawing early from the study, a recruitment target of 66 participants was set for each group.

For peer review only

RESULTS

Recruitment commenced in June 2009 and ended in September 2011. The planned study period of two years was extended by three months due to difficulties in recruitment. Figure 2 shows the flow of participants. There were 724 patients assessed for eligibility at phone screening and/or visit 1; of these, 338 failed to meet the inclusion criteria and 205 declined to participate (see online supplement). There were 181 participants randomised prior to visit 2 based on initial eligibility at visit 1; 91 to the paracetamol group and 92 to the placebo group. 53/91 participants allocated to the paracetamol group and 34/92 allocated to the placebo group were withdrawn at visit 2 as they either did not meet the inclusion/exclusion criteria ($PC_{20} > 16\text{mg/ml}$, $n=68$; $PC_{20} < 0.125\text{mg/ml}$, $n=3$; $FEV_1 < 70\%$ predicted, $n=6$; unable to perform spirometry, $n=1$) or were lost to follow-up or withdrew consent ($n=9$). No study medication was dispensed to the participants who were withdrawn at visit 2 (see online supplement).

Medication was dispensed to 94 participants who commenced the intervention phase following visit 2: 36 randomised to paracetamol and 58 to placebo. The characteristics of the subjects are shown in Table 1. The mean age of participants was 40 years and there were 59 female participants. Approximately 30% of study participants were prescribed inhaled corticosteroids and 18% prescribed long-acting beta agonist drugs. Around 90% of participants had positive skin prick tests to either cat, mixed grass or house dust mite. Participants had mild to moderate asthma, with a baseline ACQ score of 0.86 (SD 0.59). The baseline mean FeNO was 48.9 ppb (SD 41.3) and the mean FEV_1 was 94% of predicted (SD 12.0). The baseline mean PC_{20} was 4.29 mg/ml (SD 4.54).

There were 85/94 participants who completed the study. Five participants were withdrawn from the paracetamol group; two withdrew at the participant's own discretion, one was excluded due to a raised ALT (119 IU/L), one was lost to follow-up and one was excluded due to intercurrent illness. Four participants were withdrawn from the placebo group; two were excluded due to a raised ALT

(207 and 227 IU/L respectively), one withdrew at the participant's own discretion and one was lost to follow-up.

Primary Outcome Variable

At 12 weeks the mean (SD) logarithm base two PC₂₀ was 1.07 (2.36) in the control group (N=54) and 0.62 (2.09) in the paracetamol group (N=31). After controlling for baseline PC₂₀, the difference (expressed as a doubling dose difference, paracetamol minus placebo) was not statistically significant: -0.48 (95% CI -1.28 to 0.32), P=0.24 (Table 2).

Secondary Outcome Variables

There were no statistically significant differences in FEV₁, FEV₁ % predicted, ACQ score, mean morning peak flow or PEF_{var} between the control and paracetamol groups at Week 12 (Table 2) or in FEV₁ or ACQ score at Week 6 (Online Supplement). There were three asthma exacerbations in the placebo group and none in the paracetamol group, an absolute difference of 5.6% (95% CI -0.5 to 11.7%). There was 93.2% compliance in the control group and 90.8% compliance in the paracetamol group when assessed by pill count and medication diaries, a difference of 2.4%, (95% CI -1.0 to 5.8). Serum paracetamol levels (greater than the 30 µmol/L threshold) were detectable in between 31.3 to 38.7% of participants in the paracetamol group and were undetectable in all participants in the placebo group between week 2 and week 12 of the study.

There were no statistically significant differences observed in log FeNO at Week 6 (see Online Supplement), or at Week 12, or in log eosinophil or log IgE levels between the two groups at week 12 (Table 3). Only a proportion of participants had measurable levels of IFN- γ , IL-4, IL-5 and IL-13 at baseline or at other times throughout the trial, precluding meaningful analysis (see online supplement). ALT levels were significantly higher in the paracetamol group, with a mean ALT of 25.4 (SD 9.7) and 19.0 (SD 6.0) in the paracetamol and placebo groups respectively at visit 4, difference 6.3 (95% CI 2.9 to 9.7, p <0.001).

DISCUSSION

This double-blind, randomised, placebo-controlled, parallel group study found no statistically significant [reduction in PC₂₀, increase in BHR](#) with 12-weeks paracetamol treatment. However, the results did not rule out a clinically significant effect, with the 95% confidence interval containing the pre-specified difference of one doubling dose reduction in PC₂₀. There were no significant differences observed in any of the pre-specified secondary outcome variables of asthma control, inflammatory or immunological markers.

This is the first reported randomised placebo-controlled trial of the effects of daily paracetamol in stable adult asthma. The only other published randomised controlled trial of paracetamol and asthma was the Boston University Fever Study.[18] Children randomised to the ibuprofen group had a reduced risk of having an outpatient visit for asthma during the 4 week study period (OR 0.56, 95% CI 0.34 to 0.95) compared with children in the paracetamol group. Because the study did not include a placebo treatment, it was not possible to determine whether the observed difference in morbidity according to treatment group was attributable to an increased risk with paracetamol or a decreased risk with ibuprofen.

There are several methodological issues relevant to the interpretation of our study findings. First, as enshrined in the Declaration of Helsinki [\[3637\]](#) there is a requirement to study the least vulnerable populations wherever applicable. Most, but not all, of the putative adverse effects of paracetamol on asthma have been shown in observational studies of children and suggest that paracetamol may increase the risk of developing asthma.[1,2] However, as there is some data to suggest that regular paracetamol use may lead to a deterioration in asthma control in adults,[1,10] we opted to firstly examine the effects of paracetamol in adults with stable asthma.

Second, this trial was powered to determine whether there was an effect on BHR of at least one-doubling dose reduction in PC₂₀ MCh. Our ability to achieve the designated sample size completing

1
2
3
4
5
6 the study was affected by several factors. First, despite a rigorous recruitment campaign during
7 which over 700 patients were screened, due to the inclusion and exclusion criteria employed to
8 ensure participant safety, only 94 screened participants were dispensed randomised medication.
9
10 Secondly, variability in PC₂₀ from baseline to week 12 was larger than anticipated, with a pooled
11 SD of 2.27 doubling doses compared to that used in the sample size calculation based on a SD of
12 1.9, derived from previous studies.^[3536] Another factor which affected the study power was the
13 requirement to randomise subjects prior to their final screening visit in order to allow the pharmacy
14 adequate time for dispensing at visit 2, following final determination of eligibility. If the participant
15 failed this final eligibility, the randomised medication was not dispensed, the participant was
16 withdrawn from the study, and the randomisation code was not reused. By chance this resulted in
17 a disparity between the proportion of participants receiving active or placebo study medication. The
18 power was reduced further due to the withdrawal of 10% of participants following randomisation.
19 As there is an uncertain association between observed variables and missing BHR data in these
20 participants, it was not possible to perform a robust imputation.

21
22 Compliance was high when measured via pill count, and although less than half of participants in
23 the paracetamol group had measurable levels of paracetamol in the blood at the times tested
24 throughout the study, this is likely to be due to the laboratory cut-off for a detectable paracetamol
25 level (30 µmol/L). Following a 1g dose, participant blood levels may fall below this laboratory cut-
26 off level in as little as 3 hours (given an paracetamol half-life of 2 hours and a peak plasma
27 concentration 1 hour after administration of 80 µmol/L ^[3738]). The use of this laboratory cut-off for
28 paracetamol levels meant that it was not possible to investigate medication compliance through
29 this method.

30
31 Our 12-week dosing period was chosen based on evidence that regular, long-term use of
32 paracetamol is associated with an increased risk of asthma in adults [9-11,16,17] and that chronic
33 ingestion of therapeutic doses can reduce serum antioxidant capacity in as little as two
34 weeks.^[3839] We had originally intended to use the maximum daily dose of 4g paracetamol,
35
36

1
2
3
4
5
6 however chose to administer half this dose due to concerns of liver toxicity. These concerns were
7 based on a previous clinical trial of paracetamol in which the incidence of ALT elevations more
8 than three times the upper limit of normal in healthy participants taking 4g/day for 14 days was 31
9 to 44%.^[3940] Our results showed no clinically significant liver function derangement with
10 paracetamol administered at a dose of 2g/day for 12 weeks.
11
12
13

14
15
16 Whilst the study did not demonstrate a statistically significant effect of paracetamol on BHR to
17 MCh, the results do not rule out a clinically significant effect, with the upper 95% confidence
18 interval of a 1.28 doubling-dose worsening in BHR containing the pre-specified difference of one
19 doubling-dose. Furthermore, our point estimate of a reduction in PC₂₀ of 0.48 of a doubling-dose
20 could potentially be of major public health significance. As proposed by Mitchell,^[4041] a small shift
21 to the left of the BHR curve in a population could lead to a relatively large increase in the
22 prevalence of severe asthma. Relevant to the interpretation of our findings it has recently been
23 calculated that a one half doubling dose increase in BHR increases the prevalence of moderate
24 and severe BHR by about 30%.^[4142] Likewise, although the 9% increase in FeNO with
25 paracetamol was not statistically significant, a change of this magnitude is considered clinically
26 significant.^[4243] For FEV₁, the point estimate was consistent with a lower value in the
27 paracetamol group, however the difference was of uncertain clinical significance and was
28 associated with wide confidence intervals.

33
34
35
36
37
38
39

40 No significant effect was seen on serum IgE or peripheral blood eosinophil levels. It was not
41 possible to undertake any meaningful analysis of the cytokine measurements, due to the low
42 numbers of participants with detectable levels, and as a result we were unable to determine if
43 paracetamol influenced the Th1/Th2 balance. Another less recognised potential mechanism of
44 action, which was not directly assessed in this study, relates to neurogenic inflammation of the
45 airways through the stimulation of the transient receptor potential ankyrin-1 (TRPA-1) cation
46 channel by NAPQI, the metabolite of paracetamol.^[26] This pathway, which is activated following
47 therapeutic doses of paracetamol, mediates a non-eosinophilic inflammatory response and has
48
49
50
51
52
53
54

1
2
3
4
5
6 been implicated in the pathogenesis or provocation of asthma by isocyanates, aldehydes, cigarette
7 smoke and chlorine.^[4344,4445]
8
9

10
11 Our findings provide information on which the design of further studies could be based. A trial of
12 similar design, utilising the same duration and dose of paracetamol and with BHR testing to MCh
13 as the primary outcome variable, based on the standard deviation derived from this study, would
14 require a sample size of approximately 650 to attain adequate power to detect a difference of 0.5
15 doubling-doses. Alternatively, a study of short-term use of paracetamol at higher doses could be
16 undertaken, to more closely replicate the common use of paracetamol for relief of fever or pain in
17 self-limited illnesses. Based on our findings, a sample size of 140 would be adequate to determine
18 a 0.5 doubling-dose difference in MCh BHR, and a 10% increase in FeNO, in a short-term study of
19 cross-over design. Important issues with the design of such a study are the duration of both the
20 treatment periods and the crossover period. It would be important if possible to include a placebo
21 rather than ibuprofen arm, as NSAIDs may have the potential to both cause NSAID-induced
22 bronchospasm, as well as reducing asthma severity with long term use.^[29]
23
24
25
26
27
28
29
30
31
32

33
34 Finally, our study investigated the effect of paracetamol on asthma severity and not whether
35 paracetamol has a role in the pathogenesis of asthma. Testing this hypothesis would require a
36 clinical trials both of the effect of paracetamol use in pregnancy on the development of asthma in
37 childhood, and the effect of paracetamol use in infants and older children and subsequent asthma
38 risk. ~~which~~ Such studies would raise ethical and practical issues regarding consent and the use of
39 placebo for the management of pain or fever during pregnancy and in young children. However
40 given the common usage of paracetamol in all age groups including pregnancy and the global
41 burden of asthma, we propose that randomised controlled trials are required to determine the
42 effect of paracetamol use on the development of asthma in infancy and early childhood.
43
44
45
46
47
48
49
50

51 In conclusion, this study has shown no significant effect of 12 weeks of treatment with paracetamol
52 at half the maximum therapeutic daily dose on BHR and asthma control in adults with well
53
54

1
2
3
4
5
6 controlled asthma. Whilst this outcome provides some reassurance that regular paracetamol use
7
8 has no marked deleterious effect in adult asthma, further adequately powered studies are needed
9
10 before the safety of paracetamol for patients with asthma is assured. Furthermore, the study
11
12 findings do not preclude an effect of paracetamol on the development of asthma in infancy,
13
14 childhood or adult life.

METHODOLOGY

Randomisation

A computer-generated randomisation schedule was generated by the study statistician and was administered by the study pharmacists. It was necessary to randomise the subjects prior to their final eligibility screening visit (visit 2) to enable the study pharmacists adequate time to prepare the study medication for dispensing at visit 2 following final determination of eligibility. Pharmacists received notification from the study investigators that a participant was due to attend visit 2, and assigned the appropriate treatment group to the participant based on the randomisation schedule. Allocated medication was then delivered to the MRINZ research offices in labelled medication bottles, ready for dispensing to study participants at the end of visit 2 if they were eligible for the study. If a participant failed one of the eligibility criteria at visit 2, the randomised medication was not dispensed and the participant was withdrawn from the study. The randomisation code was not re-used.

Skin Prick Testing

Skin prick testing was undertaken to grass (grass mix #7, Hollister Stier Laboratories, USA), house dust mite (*Dermatophagoides pteronyssinus*, Hollister Stier Laboratories, USA), cat pelt (Stallergenes Laboratories, France), and positive (histamine) and negative controls (Hollister Stier Laboratories, USA), performed in accordance with Australasian Society of Clinical Immunology and Allergy (ASCIA) guidelines (Australasian Society of Clinical Immunology and Allergy 2006 (Revised March 2009)).

Methacholine Challenge Testing

Participants were asked to withhold long-acting beta-agonists (LABAs) for 48 hours and short-acting beta-agonists (SABAs) and food or drink containing caffeine for eight hours prior to BHR testing. Methacholine (provocholine) was sourced from Methapharm Inc

(Ontario, Canada) as 1280mg vials, and was diluted with normal saline in a sterile manner, and refrigerated at a concentration of 128mg/ml for a period of up to three months. Methacholine was further diluted for each individual challenge test into doubling concentrations of 0.0125, 0.03, 0.06, 0.125, 0.05, 1, 2, 4, 8, 16, and 32mg/ml and left to warm to room temperature for at least 30 minutes prior to each test. An English Wright nebuliser (Roxon Meditec, Montreal, Canada) was used to deliver the methacholine dose. Basic spirometry was performed prior to challenge testing, and a saline (diluent) dose was given prior to the first methacholine dose. At each inhaled dose, the subject was asked to breath normally through the mouthpiece (with nose clip in place) for two minutes, after which time FEV₁ was measured at 30s and 90s. The next concentration of methacholine was then administered within 5 minutes of the original dose commencement. If FEV₁ fell by $\geq 20\%$ from baseline (or if subject finished all concentrations without a drop in FEV₁), no further medication was given and nebulised salbutamol (5mg/2.5ml) was administered immediately, followed by a 10-minute rest period. The subject was monitored and salbutamol nebuliser repeated if necessary until FEV₁ was within 10% of post-saline baseline. PC20, defined as the provocation concentration of inhaled methacholine required to produce a 20% reduction in FEV₁ was calculated via the formula:

$$\text{Logarithmic PC20} = \text{Antilog} [(20-R1)(\log C2-\log C1)/(R2-R1) + \log C1]$$

where C1 is the methacholine concentration producing less than a 20% Fall in FEV₁ and C2 is that producing a greater than 20% fall in FEV₁. R1 and R2 are the percent FEV₁ reductions produced by C1 and C2 respectively (Cockcroft, Murdock et al. 1983).

Liver Function Tests

Liver function tests included alanine aminotransferase (ALT), alkaline phosphatase (ALP), bilirubin, albumin, total protein and gamma-glutamyl transferase (GGT). Any

1
2 participant who developed an elevation in ALT of greater than three times the upper limit
3
4 of normal during the study period was withdrawn from the trial. Blood tests to monitor liver
5
6 function were undertaken at two and four weeks after randomisation and were
7
8 accompanied by a phone call to the participant to monitor adverse events. Participants
9
10 who experienced a rise in ALT two to three times the upper limit of normal during the first
11
12 six weeks of the study were required to have additional blood tests to monitor liver
13
14 function eight and 10 weeks after randomisation. In order to maintain investigator
15
16 blinding, results of liver function tests were kept from the study investigators and viewed
17
18 only by the allocated safety data reviewers (JT and PS). If further blood tests were
19
20 required at weeks eight and 10, contact was made with the participant by the safety
21
22 reviewer directly so as to maintain investigator blinding. If, during the course of the study,
23
24 any participant was found to have abnormal liver function which required their withdrawal
25
26 from the study, the safety investigator unblinded the participant in order to inform their
27
28 ongoing management and notified their health care provider.
29
30
31
32
33

34 **Cytokine Measurement**

35
36 Concentrations of IFN- γ , IL-4, IL-5 and IL-13 were measured by ELISA (Quantikine, R&D
37
38 Systems, Minneapolis, MN), according to the manufacturer's protocols. The ELISA
39
40 minimum detectable level for IFN- γ was 12.5 pg/ml, for IL-4 was 27.7 pg/ml, for IL-5 was
41
42 3.5 pg/ml and for IL-13 was 55.3 pg/ml.
43
44
45
46
47

48 **Medication Compliance Monitoring**

49
50 Compliance with study medication was determined by a review of the medication diary, a
51
52 count of the units of medication returned at the end of the first and second 6-week study
53
54 period, and blood paracetamol levels taken at weeks 2, 6 and 12.
55
56
57

58
59 At visit 3 and 4, participants returned their medication diary and any remaining study
60
medication from the first or second 6-week period of the study. All participants were given

1
2 188 tablets of study medication at visit 2 and visit 3, which equated to 6 weeks of fully
3
4 compliant medication dosing and one extra week in case of a delay in follow-up. The
5
6 number of days that the participant had been randomised, and therefore the number of
7
8 doses of study medication expected to have been consumed over that time period were
9
10 calculated based on the entries in the medication diary. The remaining tablets of study
11
12 medication were then counted and were compared with the number of tablets expected to
13
14 be returned.

Table E1: Participant recruitment failures**Excluded at Phone Screen (n=486)**

200	Declined to participate
56	Smoker/Ex-smoker
39	Contraindication to trial/paracetamol (incl: planned surgery, use of contraindicated meds, chronic pain conditions, allergy to NSAIDS/paracetamol)
37	Asthma too severe
35	Currently using regular paracetamol
35	Asthma too mild/no asthma
34	Unable to travel to study site
18	History suicide attempt/current depression
10	Breastfeeding, pregnant, no contraception
8	Trial period ended
7	History of liver disease
6	Age outside range
1	High weekly alcohol intake

Excluded at Visit 1 (n=57)

19	FEV ₁ <70% predicted
11	Raised ALT
10	History suicide attempt/current depression
5	Lost to follow up/withdrew consent
4	Smoker/ex-smoker>10py
3	Contraindication to trial/paracetamol (incl: planned surgery, use of contraindicated meds, chronic pain conditions, allergy to NSAIDS/paracetamol)
2	High weekly alcohol intake
1	No contraception
1	High blood pressure
1	Age outside range

Excluded at Visit 2 (n=87)

68	PC ₂₀ > 16 mg/ml
9	Lost to follow up/withdrew consent
7	FEV ₁ < 70% predicted
3	PC ₂₀ < 0.0125 mg/ml

CONSORT 2010 checklist of information

Page numbers refer to the page in the manuscript [top right of document]. OS: Online supplement. P: Protocol, N/A: Not applicable

Section/Topic	Item No	Checklist item	Reported on page No
Title and abstract			
	1a	Identification as a randomised trial in the title	1
	1b	Structured summary of trial design, methods, results, and conclusions (for specific guidance see CONSORT for abstracts)	2-3
Introduction			
Background and objectives	2a	Scientific background and explanation of rationale	4
	2b	Specific objectives or hypotheses	5
Methods			
Trial design	3a	Description of trial design (such as parallel, factorial) including allocation ratio	6-8, Fig 1
	3b	Important changes to methods after trial commencement (such as eligibility criteria), with reasons	N/A
Participants	4a	Eligibility criteria for participants	6
	4b	Settings and locations where the data were collected	6-8
Interventions	5	The interventions for each group with sufficient details to allow replication, including how and when they were actually administered	7-8
Outcomes	6a	Completely defined pre-specified primary and secondary outcome measures, including how and when they were assessed	8, OS
	6b	Any changes to trial outcomes after the trial commenced, with reasons	None
Sample size	7a	How sample size was determined	10
	7b	When applicable, explanation of any interim analyses and stopping guidelines	None
Randomisation:			
Sequence generation	8a	Method used to generate the random allocation sequence	7
	8b	Type of randomisation; details of any restriction (such as blocking and block size)	7
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence (such as sequentially numbered containers), describing any steps taken to conceal the sequence until interventions were assigned	7
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned participants to interventions	7, OS

1				
2	Blinding	11a	If done, who was blinded after assignment to interventions (for example, participants, care providers, those assessing outcomes) and how	7
3				
4		11b	If relevant, description of the similarity of interventions	7
5	Statistical methods	12a	Statistical methods used to compare groups for primary and secondary outcomes	9
6		12b	Methods for additional analyses, such as subgroup analyses and adjusted analyses	9
7				
8				
9	Results			
10	Participant flow (a diagram is strongly recommended)	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analysed for the primary outcome	11, Fig 2
11		13b	For each group, losses and exclusions after randomisation, together with reasons	11, Fig 2, OS Table 1
12				
13	Recruitment	14a	Dates defining the periods of recruitment and follow-up	11
14		14b	Why the trial ended or was stopped	11
15	Baseline data	15	A table showing baseline demographic and clinical characteristics for each group	Table 1
16	Numbers analysed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups	11,12
17				
18	Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as 95% confidence interval)	11,12, Tables 2 and 3
19		17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended	11,12
20	Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing pre-specified from exploratory	OS Tables 2 and 3
21	Harms	19	All important harms or unintended effects in each group (for specific guidance see CONSORT for harms)	11,12
22				
23	Discussion			
24	Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and, if relevant, multiplicity of analyses	13-15
25	Generalisability	21	Generalisability (external validity, applicability) of the trial findings	13
26	Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence	15,16
27				
28	Other information			
29	Registration	23	Registration number and name of trial registry	3
