ABSTRACT

Objective: To determine the long-term effectiveness of a complex intervention in primary care aimed at improving outcomes for patients with coronary heart disease.

Design: A 6-year follow-up of a cluster randomised controlled trial, which found after 18 months that both total and cardiovascular hospital admissions were significantly reduced in intervention practices (8% absolute reduction).

Setting: 48 general practices in the Republic of Ireland and Northern Ireland.

Participants: 903 patients with established coronary heart disease at baseline in the original trial.

Intervention: The original intervention consisted of tailored practice and patient plans; training sessions for practitioners in medication prescribing and behavioural change; and regular patient recall system. Control practices provided usual care. Following the intervention period, all supports from the research team to intervention practices ceased.

Outcome measures: *Primary outcome:* hospital admissions, all cause and cardiovascular; *secondary outcomes:* mortality; blood pressure and cholesterol control.

Results: At 6-year follow-up, data were collected from practice records of 696 patients (77%). For those who had died, we censored their data at the point of death and cause of death was established. There were no significant differences between the intervention and control practices in either total (OR 0.83 (95% CI 0.54 to 1.28)) or cardiovascular hospital admissions (OR 0.91 (95% CI 0.49 to 1.65)). We confirmed mortality status of 886 of the original 903 patients (98%). There were no significant differences in mortality (15% in intervention and 16% in control) or in the proportions of patients above target control for systolic blood pressure or total cholesterol.

Conclusions: Initial significant differences in the numbers of total and cardiovascular hospital admissions were not maintained at 6 years and no differences were found in mortality or blood pressure and cholesterol control. Policymakers need to continue to assess the effectiveness of previously efficacious programmes.

Trial registration number: Current Controlled Trials ISRCTN24081411.

Strengths and limitations of this study

- Strengths include the original study design, the sample size and the length of follow-up.
- The significant differences in the numbers of total and cardiovascular hospital admissions observed at the end of the initial intervention period were not maintained at 6 years, pointing to a need for research into the potential benefit of delivering previously efficacious interventions intermittently over time, based on regular assessments of incentive effects.
- The main limitation to this study is that common to all trial follow-up studies: crossover between the intervention and control practices, in terms of the management of secondary prevention, could have occurred on study cessation at 18 months.

INTRODUCTION

Secondary prevention of coronary heart disease (CHD), which aims to prevent acute coronary events and optimise well-being among those with established CHD, is widely advocated and promoted. Secondary prevention is multifaceted, including pharmaceutical interventions to manage blood pressure and cholesterol and interventions to change behaviour and lifestyle. Health systems in developed countries now invest considerable, and recurrent, resources in cardiac secondary prevention.

General practice plays an important role in secondary prevention. Two systematic reviews of cardiac secondary prevention programmes have demonstrated improved process (eg, cholesterol management) and outcome (eg, mortality).^{1 2} However, both noted that there was some evidence of a 'ceiling effect' whereby interventions have a diminishing beneficial effect once certain levels of risk marker management are reached. Clark *et al*² and McAlister *et al*³ also recommended a rigorous evaluation of long-term clinical and economic outcomes.

An important contributor to the first review was our own SPHERE cluster randomised controlled trial. We found that a complex 18-month intervention with tailored plans for general practices and patients, which aimed to improve outcomes for patients with CHD, resulted in significantly reduced hospital admissions but showed no other benefits, possibly because of a ceiling effect. The current follow-up study is intended to contribute to an ongoing systematic review of long-term follow-up studies of primary care organisational interventions for the secondary prevention of ischaemic heart disease.⁴

We now report follow-up of the SPHERE participants after 6 years to first determine if the positive impact of our 18-month intervention on hospital admissions for patients with established CHD persisted and, second, to determine the long-term impact on mortality and on blood pressure and cholesterol control.

METHODS

We reported full details of recruitment, randomisation and the intervention previously.⁵ Briefly, in 2004–2005, we recruited 48 randomly selected general practices in the Republic of Ireland and Northern Ireland. In each practice, patients with established CHD, determined by documented myocardial infarction, coronary artery bypass grafting, angioplasty or angina (confirmed by exercise stress test, isotope test or coronary angiogram), were identified. Patients with a major mental or physical illness that would impair their ability to take part in the intervention (as determined by the general practitioner (GP)) were excluded. Randomly selected eligible patients were invited to participate and were asked to return study postal questionnaires. Following baseline data collection, practices were randomised to intervention and control by an individual independent of the research team.

INTERVENTION

The intervention consisted of: (1) tailored practice plans (action plans for practices were developed and reviewed; practices received a regular SPHERE study newsletter); (2) two training sessions for practitioners in medication prescribing and behavioural change; (3) tailored patient care plans (patient information booklet provided; patients identified one aspect of secondary prevention to focus on; goals and action plans developed; progress reviewed) and (4) regular patient recall system established where patients were invited to consult with the GP or practice nurse every 4 months. The intervention was developed on the basis of a review of the literature and psychological theory, mainly social cognitive theory, and modelled following qualitative research and piloting.⁶ Control practices continued with usual care⁵ and, following the intervention period, all supports from the research team to intervention practices ceased.

FOLLOW-UP

In 2012, 6 years after randomisation, we traced the original participants through their general practices and obtained their consent to collect data from their practice records. For those who had moved practice within Ireland, we made every attempt to follow them to their new practices. Patients who moved abroad were lost to follow-up.

From the practice records, research nurses collected data on risk factors, medication prescribing, hospital admissions and length of stay and on coronary events and procedures. Owing to resource limitations, only four of the five research nurses were blinded to the group allocation. Blood pressure and cholesterol data recorded in the practice records within 12 months of the end of the follow-up period were accepted.

For those who had died, we censored their data at the point of death and obtained confirmation of the cause of death from the General Registry Office (Republic of Ireland) or from the practice records (Northern Ireland). This study was approved by the Irish College of General Practitioners and the Office of the Research Ethics Committees Northern Ireland.

OUTCOME MEASURES

The primary outcome measure was hospital admissions from practice records. These were calculated for both all cause and cardiovascular related. An admission was attributed to a cardiovascular cause only if a cardiovascular diagnosis or procedure was stated as a primary reason for an admission. Secondary outcomes included mortality and blood pressure and cholesterol control. Mortality was also calculated for both all cause and cardiovascular related. A death was attributed to a cardiac cause only if the primary cause of death was cardiac. Lack of control was defined as follows: systolic blood pressure >140 mm Hg, diastolic blood pressure >90 mm Hg and cholesterol level >5.0 mmol/L.

SAMPLE SIZE

Detailed sample size calculations for the original trial are described elsewhere.⁷ We achieved the original intended sample size.

STATISTICAL ANALYSIS

The design employed was that of a longitudinal cluster randomised trial with inpatient hospital admissions, a count variable, as the primary response.

Initially, a Poisson regression model was used. Since many participants had no admissions in a given time period, two approaches were then used to adjust for overdispersion: a zero inflated Poisson regression model and a Hurdle model. All models incorporated random effects for clustering in the data due to randomisation by general practice and for the correlation due to the repeated measurements for each individual across time.

The Hurdle model⁸ splits the problem into two parts: initially, the presence and absence of admissions are modelled using a logistic component and then the mean count, for those with at least one admission, is modelled using a (truncated) Poisson regression. Therefore, whether a hospital admission occurs is considered first, followed by then describing the mean number of admissions observed. We only report the results of the logistic component of the Hurdle model in this paper; the zero inflated Poisson regression gave similar conclusions (data available from authors). There were no baseline data on cardiovascular admissions, so the total hospital admissions were used as a proxy based on the assumption that the proportion of cardiovascular and non-cardiovascular admissions was the same in the intervention and control groups before baseline.

Linear and non-linear mixed models, which accounted for missing values, were used to model the variability in continuous (eg, blood pressure) and categorical (eg, proportions outside secondary prevention guidelines) responses, using prespecified variables (GP cluster, baseline response, practice size, practice location, age, gender, years since diagnosis and conditions at baseline: angina, MI, CABG, PTCA and diabetes). The log rank test was used to compare survival distributions. All

analyses were carried out using R (2.15), using the nlme, lme4, glmmADMB, ggplot2 and survival libraries.

RESULTS

Table 1 shows that characteristics of the 48 practices and the 903 participants enrolled in the original SPHERE study were well balanced at baseline, apart from occupational status and educational level.

Figure 1 shows the flow of practices and patients through the study. For everyone alive at 6 years, follow-up was exactly 6 years from baseline. No practices were lost to follow-up. Data were collected from the practice records of 696 patients, 339 (76%) in the intervention group and 357 (78%) in the control group. It was not possible to collect follow-up practice record data for 207 patients: in total, 68 did not respond to the invitation to participate, 31 declined to participate, 78 were not contactable and 30 died during the original intervention period—all equally divided across arms. Of the original 903 patients, mortality status was confirmed for 886 (435+451 (98%)).

HOSPITAL ADMISSIONS

There were a large number of patients with no admissions in any given time period (70–84%). Table 2 shows

Table 1 Characteristics of the practices and patients at baseline

Characteristic	Intervention number (%)	Control number (%)
Practice factors		
Number of practices	24	24
Practice size		
<2 whole time equivalents	9 (47)	10 (53)
≥2 whole time equivalents	15 (52)	14 (48)
Region		
Northern Ireland	8 (33)	8 (33)
Republic of Ireland	16 (67)	16 (67)
Patient factors		
Number of patients	444	459
Men	312 (70)	321 (70)
Mean (SD) age (years)	68.5 (9.3)	66.5 (9.9)
Mean (SD) years since diagnosis	8.3 (6.6)	8.2 (6.5)
Myocardial infarction	220 (50)	233 (51)
Angina	390 (88)	414 (90)
Diabetes	78 (17.6)	82 (17.9)
Coronary artery bypass grafting	114 (25.7)	124 (27.1)
PTCA	126 (28.4)	149 (32.6)
Eligible for General Medical Scheme*	234 (82.4)	218 (73.4)
Married	288 (67)	315 (70)
Manual occupation†	134 (42)	172 (51)
Completed secondary education†	179 (42)	145 (33)
Physiological variables		
Mean (SD) systolic blood pressure (mm Hg)	136.2 (22.2)	136.8 (21.2)
Mean (SD) diastolic blood pressure (mm Hg)	78.4 (12.0)	79.5 (11.3)
Mean (SD) total cholesterol (mmol/L)	4.40 (0.90)	4.34 (0.92)

*Republic of Ireland only. Primary healthcare is free through the General Medical Services scheme only to those judged less able to pay for such services—approximately one-third of the Irish population.

†Variables prespecified as covariates in the analysis.

Figure 1 Flow of practices and patients through the 6-year study period. *No response*: participants to whom an invitation to take part in the follow-up study was sent but who did not respond. *Uncontactable*: participants who were not invited, for a variety of reasons, to take part in the follow-up, for example, the GP advised not to contact due to severe illness, onset of dementia, family bereavement or where a participant moved general practice and contact details were no longer available.

the mean number of all-cause admissions and table 3 shows the mean number of cardiovascular hospital admissions for all patients across all time points.

Admission counts were converted to annualised values when applying the linear mixed models, to make the responses equivalent measures. The results from the logistic component of the Hurdle model (table 4) show that, for both all-cause and cardiovascular admissions, the significant differences found in the original SPHERE study at 18 months persist in the 12-month equivalent analysed here, but are not apparent at 24, 36, 48, 60 or 72 months.

MORTALITY

There was no evidence that total or cardiac mortality at 6-year follow-up differed between the intervention and control groups, with 15% deceased in the intervention group and 16% in the control group (χ^2 test, $p=0.83$) (table 5). There was no difference in survival functions between the two groups (Log Rank test, $p=0.68$).

BLOOD PRESSURE AND TOTAL CHOLESTEROL CONTROL

Table 6 shows the percentage of participants outside appropriate secondary prevention risk marker guidelines

Table 2 Mean number of all-cause hospital admissions at each time point

Time point	Intervention			Control		
	N	Mean	SD	N	Mean	SD
Baseline	440	0.30	0.59	452	0.44	0.77

48	0.87	0.58 to 1.31	0.51	0.74	0.43 to 1.29	0.29
60	1.19	0.79 to 1.80	0.40	1.39	0.81 to 2.40	0.23
72	0.83	0.54 to 1.28	0.40	0.91	0.49 to 1.65	0.75

*OR adjusted for GP cluster, baseline inpatient admissions, practice size, practice location, age, gender, years since diagnosis and conditions at baseline: angina, MI, CABG, PTCA and diabetes.

†Data were originally collected at the end of the 18-month intervention and the first follow-up period was 6 months, so these are based on annualised equivalents of the admission counts.
GP, general practitioner.

at baseline and at 18 months and 6 years. The proportion of patients outside of the recommended guidelines decreased from baseline to 6-year follow-up, but the differences between groups were not significant.

DISCUSSION

We found that after 6 years of follow-up of patients with established heart disease randomised to a complex intervention with tailored plans for general practices and patients or usual care, initial significant differences at 18 months in the numbers of all-cause and cardiovascular hospital admissions were not maintained. At the 6-year follow-up, there were also no differences in mortality or blood pressure and cholesterol control.

Three other equivalent studies have reported similar follow-up periods: Cupples in Belfast,⁹ Murchie in north east Scotland¹⁰ and Munoz in Catalonia.¹¹ None reported similar admission data. Murchie reported significantly lower cumulative death rates, in favour of intervention practices, of 14.5% and 18.9% ($p=0.038$). Cupples reported similar proportions; Munoz found no significant differences in mortality. We are currently conducting a systematic review of all follow-up studies of cardiac secondary prevention programmes in general practice.⁴ The Belfast and Scottish studies were initially conducted in the early and mid-1990s, respectively, when control of cardiovascular risk markers for patients with established heart disease was poorer than it is now. For example, the mean baseline cholesterol was 6.2 mmol/L in Belfast, while the mean Scottish baseline cholesterol was 6.5 mmol/L. These are much higher than what we found at baseline in 2005 (table 1), which in turn are similar to those found by Munoz *et al*¹² in 2001.

IMPLICATIONS FOR PRACTICE AND RESEARCH

As suggested by the two systematic reviews,^{1 2} it may be that with improved secondary cardiac risk profiles for both individuals and the general population, a ceiling has now been reached. Gains previously possible in risk marker management may no longer be attainable. Table 6 highlights the importance of control groups as the cholesterol and blood pressure control improved generally over time. Policymakers need to continue to assess the effectiveness of previously efficacious programmes. From an economic perspective, the additional cost of delivering the intervention for 18 months was offset by the savings generated from reduced hospital admissions, leading to an overall reduction in healthcare costs relative to control at 18 months with no impact on patient health status.¹³ Ongoing analysis for our upcoming paper on the cost-effectiveness of the SPHERE intervention at 6 years will provide further insight on this question.

The ongoing effects of incentivising or supporting interventions need to be balanced with a consideration of the opportunity costs for such incentives. Behavioural research has confirmed that the impact of a behavioural intervention diminishes once the intervention ceases.^{14 15} Research is needed into the potential benefit of intermittent incentives or support for interventions using some sort of 'turn on, turn off' approach based on regular assessments of programme or incentive effects.

LIMITATIONS

The main limitation to this study is that common to all trial follow-up studies: crossover between the intervention and control practices, in terms of the management of secondary prevention, could have occurred on study

Table 5 Total and cardiac mortality at 6 years

	Alive, n (%)	Deceased, n (%)	Cardiac cause of death, n (%)*	Not established, n (%)
Intervention	370 (83)	65 (15)	29 (45)	9 (2)
Control	378 (82)	73 (16)	32 (44)	8 (2)

*Of those who died in that study group.

Table 6 Percentage (number) of participants outside the appropriate secondary prevention risk marker guidelines at baseline and at 18 months and 6 years

Variable	Valid number at baseline/ 18 months/6 years			Baseline		18-Month follow-up		6-Year follow-up		OR (95% CI)*	p Value
	Inter	Control		Inter	Control	Inter	Control	Inter	Control		
Systolic BP >140 mm Hg	443/360/317	456/405/329		34.1 (151)	33.8 (154)	27.2 (98)	32.8 (133)	31.5 (100)	24.3 (80)	1.02 (0.73 to 1.43)	0.90
Diastolic BP >90 mm Hg	443/360/319	458/405/329		13.3 (59)	11.4 (52)	8.9 (32)	9.9 (40)	3.8 (12)	3.3 (11)	0.94 (0.01 to 113.63)	0.98
Total cholesterol >5.0 mmol/L	424/342/273	436/391/294		21.7 (92)	22.0 (96)	15.2 (52)	16.4 (64)	13.9 (38)	13.6 (40)	0.82 (0.12 to 5.40)	0.83

*OR of being outside risk marker guidelines for intervention relative to control at 6 years adjusting for baseline response, GP cluster, practice location, practice size, age, gender, years since diagnosis and conditions at baseline: angina, MI, CABG, PTCA and diabetes.
BP, blood pressure; GP, general practitioner.

cessation at 18 months. We simply do not know whether intervention practices ceased to provide the intervention, or control practices introduced similar approaches, or a mixture of both. This potentially could result in a significant difference being missed at the follow-up point and a type II error. The trends over time in [tables 4](#) and [6](#) do not suggest this. Classification of admissions into cardiovascular or not was dependent on routine admission records.

We suggest that it would be helpful if there were general guidelines on how best to report long-term follow-up studies of trials.
