WHERE CHILDREN AND ADOLESCENTS DROWN IN QUEENSLAND: A POPULATION-BASED STUDY

Keywords: drown*, child*, adolescent, incidence, non-fatal drowning

Word count: 5468
ABSTRACT

Object

This retrospective population-based study examined drowning location by the site of immersion for both fatal and non-fatal drowning events in Queensland. Drowning location is not routinely collected, and this study used data linkage to identify drowning sites. The resulting enhanced quality data quantifies drowning incidence for specific locations by geographic region, age group and by severity for the first time.

Design

Linked data were accessed from the continuum of care (pre-hospital, emergency, hospital admission and death data) on fatal and non-fatal drowning episodes in children aged 0-19yrs in Queensland for the years 2002-2008 inclusive.

Results

Drowning locations ranked in order of overall incidence were pools, inland water, coastal water, baths and other man-made water hazards. Swimming pools produced the highest incidence rates (7.31/100,000) for overall drowning events and were more often privately owned pools and in affluent neighbourhoods.

Toddlers 0-4yrs were most at risk around pools (23.94/100,000), and static water bodies such as dams and buckets – the fatality ratios were highest at these two locations for this age group. Children 5-14yrs incurred the lowest incidence rates regardless of drowning location. Adolescents 15-19yrs were more frequently involved in a drowning incident on the coast shoreline, followed by inland dynamic water bodies.
Conclusion

Linked data has resulted in the most comprehensive data collection on drowning location and severity to date for the state of Queensland. Most mortality and morbidity will be prevented by improving water safety through engaged supervision around pools and bath time, and a heightened awareness of buckets and man-made water hazards around the farm home for young children. These data provide a different approach to inform prevention strategies.
ARTICLE SUMMARY

Strengths and Limitations of this study

- Data linkage with case notes provided enhanced detail on non-fatal drowning locations and contributing factors associated with the environment of those locations.

- Incidence related to drowning locations and the effects of age on rates are reported for the first time.

- A breakdown of pool operators, static and dynamic water bodies, coastal waters, and geographic and socio-economic information provides new perspectives for drowning locations to inform prevention strategies.

- Locations in order of incidence overall were pools, inland water, coastal water, baths and other man-made water hazards.

- Heightened supervision and prevention efforts directed at developmental prevention strategies for all static water hazards close to home are required to reduce the drowning burden for toddlers 0-4yrs who have the largest drowning burden, regardless of the location. Adolescents are more likely to have drowning incidents in coastal water or inland dynamic water.
INTRODUCTION

Approximately every three minutes somewhere in the world a child aged between 0-19yrs drowns.\textsuperscript{1} These young people account for almost half of the worldwide annual total deaths, and those under the age of 5yrs are disproportionately affected.\textsuperscript{2, 3} These numbers are believed to be underestimated by 39-50\% because drowning due to natural disasters, transport incidents and intentional drowning are not included.\textsuperscript{4} These data also do not provide a measure of morbidity associated with drowning survival, nor do they provide information about where the drowning occurred.\textsuperscript{5} Current data from Queensland for children 0-19yrs established a fatal rate of 1.5/100,000, yet the non-fatal drowning rate was 13.6/100,000 pa. For every fatality ten other children were retrieved from the water and sought medical assistance.\textsuperscript{6}

The circumstances leading to drowning can vary widely, and drowning location, age of the child and the child’s activity are inevitably linked.\textsuperscript{7-10} Differences in geographical and cultural factors between high income countries (HIC) and low and middle income countries (LMIC) also exist.\textsuperscript{10, 11} In HIC, among children up to the age of one year, most drowning deaths occur in bathtubs.\textsuperscript{4, 7, 8, 12, 13} After the first year of life, swimming pools and man-made ponds (dams) or reservoirs are more frequently involved.\textsuperscript{4, 14, 15} The World Health Organisation (WHO) recognised that poor quality drowning data have contributed to a neglect of drowning as an important public health issue, and that if prevention strategies are to be successful, they need to be tailored to the local context.\textsuperscript{4} This emphasises, the importance of good quality local data such as this which identifies drowning locations.
Currently administrative data bases worldwide collect drowning information according to the International Classification of Diseases (ICD-10)\(^\text{16}\) at only three locations: baths (W65-66), pools (W67-68), bathtubs and natural water (W69-70). All other drowning locations are grouped under “specified” or “unspecified” (W73-74), which hinders injury prevention. Presently there is no international aquatic standard for the classification of water body types which makes comparisons of locations and contributing factors almost impossible between countries. In this study water type has been analysed as five categories to produce data and encourage prevention strategies that may be useful to other countries.

A further challenge to comprehending drowning is the difficulty in obtaining an accurate measure of actual exposure to water. By this we mean using a child-risk measure; that is, children who are likely to access, enter or be near water, rather than children from within a population-based group (some of whom may not necessarily be exposed to water).\(^\text{17}\) An Australian study demonstrated that when explored by actual exposure, drowning risk was under-estimated and was higher than road traffic risk.\(^\text{18}\) This exposure measure reflects temporal fluctuations, lifestyle and regional characteristics, however, obtaining such data is usually done by telephone survey, is labour-intensive, expensive and logistically only possible in High Income Countries (HIC).

Since the seminal work of Pearn and Nixon,\(^\text{19}\) and Pitt et al\(^\text{20}\) exposed unfenced backyard swimming pools and bathtubs as high risk locations,\(^\text{12,21,22}\) the 0-4yr old pool immersion rate trebled in Brisbane to 70.2 in 1986,\(^\text{23}\) and then reduced to 20.7 in in 2002.\(^\text{24}\) Therefore this is a timely detailed review that encompasses all locations (e.g. pools, dams, bathtubs, creeks and rivers) and an exploration of any contributing factors in the chain of events leading to drowning. These data assist in an understanding of drowning incidents for prevention efforts,
which must take into account child developmental factors, the characteristics of the water body, and the physical and socio-economic environments.\textsuperscript{1, 15}

The overarching aims of this paper were to identify locations of drowning events in Queensland children and adolescents, and to quantify the magnitude of fatal and non-fatal drowning at particular sites. Prevention strategies can be adopted for identified drowning sites beyond ICD-10 coding and characteristics associated with reoccurring locations and particular age groups were explored where available. This study fills a crucial gap in reporting locational incidence rates for Queensland children, and presents analyses of fatal and non-fatal drowning location data collected using data linkage. This method achieved the best possible case capture to report all drowning cases as defined internationally.\textsuperscript{25, 26} We report for the first time incidence rates for drowning locations which frequently reoccurred in Queensland, along with the severity of events and contributing factors for particular drowning environments.
METHODS

Data were obtained for all drowning episodes in Queensland where medical assistance was sought for children and adolescents aged 0-19yrs inclusive, between 1 January 2002 and 31 December 2008. For simplicity of reading, we will refer to this entire age group as children. This paper describes all drowning events, and specific drowning groups (for example those who died), as fatal drowning or non-fatal drowning, as per the internationally agreed definition, and respiratory impairment was considered to have occurred if medical assistance had been sought.

Data custodians, extraction criteria and linkage methods are described elsewhere. However in summary, identified data were manually linked to create a comprehensive dataset across the continuum of care. Cases were included once only if a patient appeared in any of the databases accessed, (patient transfers between hospital facilities were excluded) and were categorised as pre-hospital or emergency department (ED) treatment, hospital admission or death. Additionally, cases were included if the patient died at the scene or subsequently without discharge from hospital. Briefly, data on age, gender, drowning location of event, geographical event location (Accessibility/Remoteness Index of Australia (ARIA) based on event postcode), event time, and day of week were collected. Residential postcode was used to calculate Socioeconomic Index for Areas (SEIFA) and drowning event postcodes were used to determine Index of Relative Socioeconomic Advantage and Disadvantage (IRSAD). Data on non-fatal drowning locations were obtained from pre-hospital and emergency department case notes, Queensland Injury Surveillance Unit, or ICD-10 codes for hospitalised cases. These notes were also used to obtain information on other circumstances leading to the drowning event.
Descriptive analyses used six categories for drowning locations: 1. Swimming pools (referred to as pools) were considered to be any manufactured structure for swimming in public, private (including wading pools) and commercial spaces. Included in this group were spas where water is not emptied at the end of each use (as opposed to spa baths which are typically emptied after use); 2. Baths were nominated as such and included shower baths and laundry tubs where children were being bathed; 3. Coastal water included beach, surf, and rip currents (where people enter the water from the shoreline) and has been separated from inland water when it was specifically nominated as such in the text. For the purposes of analyses the coastal water category includes ocean and sea where entry to the water was from a boat or jetty, as the number of events were small (6%); 4. Inland dynamic water included creeks, rivers, weirs, streams of water, and flood water; 5. Inland static water is usually naturally occurring water bodies such as lakes, however due to their size animal water storage (dams) are included as well as those categorised as “inland water bodies” and “large area of water” or “still water” in the data. 6. Locations classified as “other” included manufactured (or man-made) hazards around the home such as buckets, tanks, ornamental ponds, drains and culverts, or animal water storage (such as troughs or dips). These generally involve smaller quantities of water and have been referred to as “other man-made water hazards”.

Private and public settings were classified by levels of access. Private settings were considered to be a domestic pool (or water body) for private use of the residents (included single and multi-dwelling pools, wading pools, outdoor spas, baths, dams). Public water settings were categorised on two levels of access: Public restricted access: Commercial/municipal operated (or developed) settings where access is restricted by opening or closing times, or to patrons who may have paid for holiday accommodation or to use the
facility, (eg. water theme parks, school pools, hotels, resorts, caravan or holiday parks; and
Public unrestricted access: where there is no fencing, or open and close times (beach, rivers,
creeks, waterholes, and tidal pools).

Drowning locations were further collapsed into four categories for the purpose of calculating
Incidence Rates (IRs). Inland water includes static and dynamic water, and due to small
numbers “other man-made hazards” was grouped with missing. The drowning locations were
stratified by Accessibility and Remoteness Index for Australia (ARIA) and severity (death,
admission to hospital, or not admitted).

Fatality ratios were the number of fatal events over the number of non-fatal events. Crude IRs
were calculated for each calendar year, using population data from the Australian Bureau of
Statistics and are expressed as per 100,000 per population. Descriptive analyses used data
on all drowning events that occurred in Queensland, and IRs were calculated for events
among Queensland residents only due to the lack of age-specific population data on non-
Queensland residents (for the denominator). Calculation of incidence rates for fatal and non-
fatal events was stratified by age, drowning location and severity. Chi square test for trends
over time were computed using Centers for Disease Control and Prevention Epi Info ™
7.1.2.0. Relative Risks (RR) and 95% Confidence Intervals were calculated using IBM
Descriptive analyses (primarily chi-square tests) were also conducted to determine whether
there were variations in characteristics of drowning events. Fisher’s Exact was used where
assumptions of chi-square tests were violated.
Ethics and approvals were sought and granted from Children’s Health Services District (Royal Children’s Hospital Human Research Ethics Committee HREC/09/QRCH/38; Royal Children’s Hospital Institutional Approval; University of Queensland Medical Research Ethics Committee #2009001463; Mater Health Services Human Research Ethics Committee #1446E; and National Coronial Information System #CF/07/13729 (2007-2010), #CF/10/25057 (2010-2013), #CF/13/19798 (2013-2016). Director General approval was granted through Public Health Application, Queensland Health 16/3/2010 Ref RD002254. Custodian approvals were granted from Royal Life Saving Society Australia, Commission for Children and Young People and Child Guardian, Queensland Ambulance Service.
RESULTS

Descriptive drowning location analyses 0-19yrs

A total of 1299 (120 fatal and 1179 non-fatal) drowning incidents among 0-19yr olds in Queensland occurred between Jan 2002 and December 2008. Differences in drowning location and age groups are shown in
Table 1 ($X^2=352.13$ df=8 $p=<0.001$) and indicate that more than half (59%) of all drowning occurred in pools, followed by inland water (13.4%), baths and coastal waters (12.5% respectively), and other man-made water hazards (2.5%). There were significant differences in drowning location by age group. The 0-4yr age group had the highest frequency of drowning in sites close to home with more than two thirds of drowning events occurring in pools (68%), and 18% in baths. For adolescents 10-19yrs more drowning events occurred at locations further from home in coastal water, followed by inland water and pools. The highest fatality ratio (0.69) for 0-19yrs was associated with other man-made water hazards; and a breakdown of these sites showed buckets as being most predominant (32%). Inland water incurred the second highest fatality ratio (dams stand out in this group with a fatality ratio of 2.67), and pools and baths the lowest. Pools generated the lowest fatality ratio indicating that children were more likely to be rescued from a pool and survive the event than any other locations. Males were over-represented in all sites except bathtubs ($X^2=13.21$ df=3 $p=0.004$). More males were involved in events in dynamic water was 1.9:1 rather than static water 1.4:1.

(%)within location; †Fatality ratio = number of fatal events/number of non-fatal events; ‡81 pools were not able to be identified as public or private; np = not publishable due to small numbers. Data on frequency of Other man-made water hazards are presented in this table but for analyses this category was collapsed into missing.

The frequency of occurrence of particular drowning sites is presented in Table 2 and the top three sites for each age group are ranked for fatal and non-fatal events. Seventy one percent of pools were identified as being operated for public, public commercial or private use. The majority of pool drowning events (67%) occurred in privately owned pools and a further 29% were in public (commercially operated) pools where access was restricted. There were no fatalities at public unrestricted access pools. Most children who got into difficulty in pools (60%) were in the water rather having fallen in at the time of the incident. However, the inverse was true for 0-4yrs olds as they were most likely (85%) to have fallen in ($X^2=15.88$ df=4 $p<0.01$). There were 68 incidents that could be identified as inland static, and 78 as dynamic water incidents.

Note for sub-categories: Pools (private, restricted access or unrestricted access); Inland water (static or dynamic); Coast (entry to water shoreline or offshore);

**Remoteness:** Error! Reference source not found. shows the proportion of drowning events that occurred at specific sites in the state of Queensland by remoteness (ARIA). Pools were the most frequent drowning location for all geographic regions, with the majority occurring in Major Cities (33%), Regional (24%) and Remote (2%) ($X^2=28.23$ df=6 $p<0.001$). All other drowning occurred at sites in similar proportions across the geographic regions.
Socio-economic status: Drowning locations varied between areas in the highest 50% of IRSAD (decile 6-10 indicating a relative advantage) compared to those in the lower 50% (decile 1-5 indicating relative disadvantage) ($X^2=22.61$ df=3 $p<0.001$). The highest frequency drowning locations in most advantaged areas were pools (64%), followed by baths (13%) and coastal waters (12%). In areas with a relative lack of advantage twice as many drowning events occurred in inland water (22% vs 11%) and other man-made hazards (4% vs 2%) than areas of advantage. Disadvantaged areas also incurred higher proportions of fatal drowning events than disadvantaged areas (14% vs 7%), and higher proportions of fatal drowning events compared with non-fatal events (43% vs 28%). ($X^2=14.717$ df=1 $p<0.001$).

Overall drowning location incidence rates 0-19y years

There were 1179 Queensland residents involved in drowning events and 981 (83%) where a drowning location was identified (Error! Reference source not found.).

Overall, the holds over the study period were in pools. This was followed by inland water, coastal water, baths and man-made water hazards.

*p<0.05; **p<0.01; ***p<0.001; Increases (↑); decreases (↓), or no change (←→) in drowning incidence over time; † Non-fatal = admissions and emergency presentations; ‡ Reference category females.

Pools had the highest IRs for all types of drowning events (Table 3). Total drowning rates (fatal and non-fatal combined) for 0-19yr olds significantly increased over the study period for pools (69%), inland water (67%), and in coastal waters (63%), whereas there were small (non-significant) decreases in rates for bath and man-made water locations. Non-fatal drowning events were a significant proportion of these increases - pools (87%), inland water (85%) and the coast (63%). There were no significant changes over time in fatal rates for any location.

The male to female ratio for all drowning events where location could be identified was 1.5:1 which varied by location ($X^2=13.21 \text{ df}=3 \ p=0.004$). Males had a greater risk of drowning than females at any location, but particularly pools and inland water. The only exception was baths where a risk of drowning was 22% lower in males than females though this was not significant ($RR=0.78 0.56-1.10$).
Location by age group and severity

**Trends over time:** There were no significant changes over the seven years in fatal rates at any of the locations in any age group. Where total incidence rates increased this was primarily due to increases in non-fatal drowning events (Table 4). Pool rates increased in every age group except for those aged less than 12 months. The most pronounced increases were 0-4yr and 5-9yr olds. Increased rates were seen in inland water drowning for 10-1yr non-fatal drowning, and coastal drowning in 5-9yr olds. For children over 2yrs bath drowning is a rare event. The highest percentage (74%) of unknown locations was in the 0-4yr age group.

*p<0.05; **p<0.01; ***p<0.001 increases (↑); decreases (↓), or no change (↔↔) in drowning incidence over time; trends only shown for Total drowning or where significant; np=not publishable due to small numbers being potentially identifiable.

Analyses for the separate locations stratified by age and severity are shown in Error! Reference source not found. and Table 5. Information on contributing factors where they were able to be identified is presented in the following text.
**Pool Drowning:** Swimming pools incurred high drowning rates in the 0-4yr age group for fatalities, admissions, and non-admissions than any of the other age groups.

The highest rates of pool drowning occurred in children aged one, two and 3yrs for total drowning events, hospital admissions and fatal events. Two year olds were the most vulnerable in terms of risk of pool drowning (IR=37.34).

RR† - Relative Risk reference group 5-19yrs; RR‡ - Relative Risk reference group Fatal (non-fatal is any drowning event – pre-hospital and admitted); IR – Incidence Rates quoted per 100,000 population per annum; np not publishable due to small numbers.
**Inland Water:** Fatal drowning occurred at this location across all age groups, (Error! Reference source not found.) however no infant <1yr fatally drowned in inland water bodies. Dams were the most common location in this category for the 1-4yr age group. Toddlers aged 1-4yrs were 2.7 times more likely to drown than their counterparts aged 5-19yrs in bodies of inland water Error! Reference source not found.. Admission rates for inland drowning were highest for 1-4yrs (IR=2.23) and <1.0 for all other ages.

**Bath Drowning:** Bath drowning was more frequent and severe in children under five years (Error! Reference source not found.). The male to female ratio for bath drowning was the same for <1yr and 2-4yrs, but females were more frequently involved in bath drowning at 1yr and seven times more frequently involved between the ages of 5-19yrs (Table 5). Ranked fourth in drowning locations overall, bath drowning incidence was the greatest for infants aged 0-1yr. The risk of a bathtub drowning event for an infant aged <1yr is 143 times that of children 5-19yrs.

Examination of case notes showed that the majority (67%) of bath drowning events occurred when there was no supervisor in the room (the child was knowingly left alone in the water even for a short time ranging from 1s to 30mins). Seven percent were left with a sibling (aged between 3-5yrs) where the sibling either did not respond to, or contributed to the drowning in some way, or alternatively alerted the parent (usually that the water was overflowing). A small percentage (5%) was the result of a seizure or intentional harm. None of the 18 cases who had direct supervision were fatal and all but one were aged <1yr.
Coastal Drowning: Fatalities from drowning at the coast were rare (IR<1) but occurred in all age groups. There were no coastal drowning fatalities for infants aged less than 1yr (Error! Reference source not found.). Drowning in coastal waters incurred the lowest total drowning rates for all children 0-19yrs. Admission rates were highest for 0-4yrs, and were <1.0 for all other age brackets. Almost half of fatal coastal events were related to watercraft, swimming alone or at night, or in rough unpatrolled surf. Almost half of all fatal watercraft victims were not wearing a life jacket. Coastal drowning events were more common in older children these events were 30% less likely for those aged 0-4yrs than 5-19yrs (Table 5).

Other man-made water hazards: (data not shown due to small numbers). This category had the lowest numbers of drowning events of all, yet the highest proportion of fatalities (41%). All fatalities occurred among 0-4yrs. There were no drowning events (fatal or non-fatal) in 5-9yrs, or 10-14yrs and non-fatal events were rare in 15-19yrs. Incidence was highest incidence in children 0-4yrs (IR=3.18) and 96% of all cases were in this age group. Admission rates for <1yr and 1-4yrs were approximately equal (IR=0.53 and IR=0.54). The majority of these locations involved static water, and buckets were the most common drowning danger (33%). Hazards such as ornamental ponds, tanks, stock troughs and stock dips presented the greatest risks for toddler drowning especially for those under one year (IR=1.34) and a risk of drowning in such water hazards was 78 times that of older children 5-19yrs (RR=78.50 95%CI 9.171-671.90). Males were twice as likely as females to drown in these types of water bodies, but this was not significant.
DISCUSSION

Drowning locations ranked in order of overall incidence were pools, inland water, coastal water, baths and lastly other man-made water hazards. The magnitude of drowning at these sites was much greater in Queensland than previously reported for the rest of Australia or the USA.29-32

Young children aged 0-4yrs had a seven-fold risk of a drowning event over 5-19yr olds,6 signifying that the high risks for drowning associated with the early developmental years need to be examined in the context of pools, baths, and inland water - particularly water storage dams and other man-made water hazards close to the home. Mortality case series have previously provided the only data on hazardous locations such as dams or buckets,33 34-37 whereas, these detailed locations provide insights for national hospitalisation data32 which lacks location detail beyond ICD-10 coding of pools, baths and natural water. Coding for more than one quarter of the 0-4yr cohort was “unspecified” and yet this age group constitutes 43% of the total all-age drowning hospitalisation in Australia.32 The detail contained in this non-fatal data points to locations around the home that are not unique to Queensland, and are eminently preventable at a national level with appropriate interventions.

The discussion which follows is presented in the context of location (or water type), the predominant age of the child affected, and any prevalent contributing factors. The results reinforce the necessity for better drowning location definitions (an aquatic standard) for the classification of water body types in coded data enabling prevention strategies to be targeted by drowning location as well as geographic regions. Such multi-level approaches can target an appropriate audience for the age group at risk, and promote specific interventions observed to have promising outcomes.10 38 39
Pools

Overall, more than half of all Queensland child drowning occurred in pools and predominantly among males. Encouraging signs of fatality prevention are that the swimming pool fatality rate is much lower than reported in 1976 (IR=0.65 vs IR=22.55), and pools incurred the lowest fatality ratio of all sites. However, the highest admission rates, and significant increases in non-fatal pool drowning rates over the reporting period, along with higher rates than previously reported in 1976 (IR=9.49 vs IR=6.2), indicate the potential for morbidity and further fatalities. There is no room for complacency. Pool drowning occurs predominantly in privately owned pools, which are more often than not located in areas of relative high socioeconomic advantage. It occurs more often in the city, but also in inner and outer regional areas as well as remote areas across Queensland.

Pool density has been shown to affect drowning although the methods to calculate it differ between pools/population-at-risk and pools/number of dwellings. An estimate of 311,000 pools and spas registered in Queensland homes per 1,660,750 dwellings gives density ratio of 1:5 which is similar to an earlier Brisbane City study. To some extent this high density of pools would explain the over-representation of this location in drowning episodes, however, this higher exposure will also require consolidation of political will and public acceptance for ever-strengthening interventions to be implemented. The Queensland Pool Registry (operating since 2010) is anticipated to not only confirm the number of pools in Queensland, but also verify the presence of pool fencing which complies with current

*(G Hemmings, A/Principal Advisor DLGP, personal email communication, March 28, 2012)*
legislation. More importantly, with an aging stock of pools in Queensland, ensuring that
fences and self-closing gates are maintained and operating is a priority.45

It is equally important to prevent young children from getting into the pool alone, but also to
protect them while they are in the water. The majority of children got into difficulty while
they were known to be in or around water however, 0-4yr olds were most likely to have fallen
in. Pool fencing was mandated in Queensland in 1991 and has been shown to be an effective
drowning countermeasure for such lapses in supervision of young children.20,46 Over the long
term, pool fatality in this age group has reduced in Queensland and this has been linked to
ever-strengthening legislation implementing standards related to pool fencing.47,48 Regulatory
control by individual local councils from 1992 led to inconsistencies in enforcement so it is
difficult to say definitively that this has reduced fatality on its own, however as the only
intervention promoted consistently over the time this is a positive sign toward reducing
drowning in this age group.

Obligatory CPR courses for all registered pool owners could provide an opportunity to
append other pool safety information about pool toys and flotation devices; the necessity for
close, constant and visual supervision.49,50 This is particularly critical for the vulnerable ages
1-3yrs. In this study dimensions of supervision ranged from “direct” (constant visual where
physical proximity to the child allowed a quick response) to “indirect” supervision (where the
supervisor knows the child is in or near water but is unable to take immediate protective
action).51 Common risk factors were reliance on siblings as caregivers, or a misguided belief
that carers would hear if trouble occurred. In the majority of these lapses (over 64%)
caregivers knowingly left the child in or near water for just a short time to tend to laundry,
food preparation or the phone.
The older age groups incurred the least pool immersions and it is not clear why they were involved in fewer events, but may be related to better swim ability, some level of supervision and/or a developing concept of water safety. Nonetheless, this was the location with the highest frequency for 5-9yr olds, leaving no room for complacency.

**Inland water**

Ranked second as a drowning location overall, this was the leading location for fatalities in children 5-19yrs. In younger children 1-4yrs dams constituted more than half (55%) of drowning locations with an astonishing fatality ratio of 2.66. In rural settings a safe fenced house yard/play area is the best way to prevent young children from wandering alone long distances to water hazards that they may have visited regularly. For adolescents 10-19yrs these settings more often involved dynamic water and was more frequently chosen for recreation than pools. Behaviour change interventions which tackle common risk factors such as over- or under-estimating ability or current strength; swimming alone or at night, or after consuming alcohol. These kinds of water settings were more often found in areas of relative low socioeconomic advantage.

**Baths**

Hospital admission following a bath drowning was second only to pool drowning in children 0-19yrs. and may be related to the young age of most bath immersions. A further breakdown of ages within the 0-4yr group indicated engaged direct supervision as lacking in the bathroom for infants <1yr. Although bathtubs ranked as the fourth location in overall drowning, a very high risk was indicated for infants <1yr (143 times 5-19yr olds). Bathtub drowning interventions are best targeted at parents of very young children as immersions are
unusual above 2yrs. Parents and carers should be reminded to never leave young children alone in the bath (even for short periods) or in the care of a sibling. Baths were the sole location where significantly more females than males had drowning events. The other age group of concern for bath drowning is adolescents 15-19yrs where intent, and the involvement of other substance use played a role.

Coastal water

Non-fatal drowning rates increased over the study period and the coastal shoreline was the second most frequent location for intervention activities for 5-9yrs. It is law that children 1-12yrs require a life jacket (PFD) when in small boats. Small watercraft incidents offshore resulting in fatality show life jacket compliance is low across all ages. Water recreation for incidents for adolescents 15-19yrs at the surf beach involved rip currents, exhaustion and alcohol. Interventions and risk factors were similar for Inland water drowning (see above).

Other man-made water hazards

These more unusual water bodies produced the highest fatality ratio and mostly occurred in children 0-4yrs (96%). Strengthened efforts are required to educate new parents that buckets left partly filled after use resulted in one third (32%) of drowning events. They are a lesser known but universal threat as are man-made water hazards such as troughs, in-ground tanks, and drains or culverts. There is scope to mitigate access at the time these water bodies are created. These were more common in areas of relatively low socioeconomics generally in line with more rural settings.

Strengths and limitations: This is the first study on drowning to comprehensively utilise linked data across the continuum of care (pre-hospital to fatality), and effectively map the
‘patient journey’ from the moment of retrieval from the water to definitive care. Drowning is a process which is the outcome of a chain of events, and data that capture patterns within that chain of events has an inherent value. The value in collecting text narratives is validated by the previously unexplored magnitude of non-fatal drowning locations that frequently reoccur. Data linkage limitations have been published previously.

This linked data is a major strength of this study and allowed identification of detailed information on drowning location. A substantial proportion of data on drowning location were obtained from case notes prepared by paramedics (eARF) who attended the scene, or text entered in the “presenting complaint” field in the emergency department. This was true even for cases resulting in hospitalisation following the drowning event, as information on these events is limited by the available ICD10 codes to the following categories: bathtub (W65-W66), swimming pool (W6-68), natural water (W69-70, with no differentiation between lake, open sea, river and stream); Other specified drowning and submersion (W73); and unspecified drowning locations (W71, a very frequently occurring code indicating it used as a garbage code). Including the pre-hospital and emergency case notes allowed calculation of incidence rates and analyses at a much more detailed level than has previously published.

The utility of the consequent linked data is great, and also allowed identification of factors that contributed to the drowning event such as supervision, swimming alone and similar other risk factors. Data on supervision and contributing factors were not analysed in detail in this paper but are planned for the future.

The authors acknowledge that coastal drowning events may be underestimated where it has been categorised as “large area of water” or “natural water”. These, along with “natural still water” have been categorised as inland static water. Age-specific population data used to
calculate rates for immersion sites may underestimate risk of drowning, however water exposure data \cite{18} and pool data \cite{42} were not available for Queensland. Further work is required in improving the collection and description of aquatic locations. It may be that some parents sought medical care for their children as a precautionary measure after the event, and this is noted when known.

In 2010 further legislation that post-dates these data introduced a register in Queensland where pool owners are obligated to register their pools, and ensure pool fencing complies with Australian standards before sale or rental of the property. Owners who don’t sell or rent had a five year window to ensure that their pool fencing complied. Certification requires updating every two years. The register utilises hospital presentation data, and any pool where a child had a drowning event and seeks medical assistance is investigated for contributing causes. We look forward to findings of these inspections to provide contributing factors to morbidity and improved fencing compliance.\cite{45}
CONCLUSION

This is the first study in Australia to link data for drowning events and explore the differences between fatal and non-fatal drowning locations by incidence, age and severity. This enhanced quality data have identified target populations, socio-economic groups, geographic regions along with contributing factors specifically related to drowning locations in Queensland. This is a different perspective to inform injury prevention strategies.

Swimming pools yielded the highest incidence rates for overall drowning events and pose the largest burden across all age groups. Swimming pools dominate the drowning burden for 0-4yrs and produced the most fatalities, admissions and affect more age groups than any other location. Older children were more frequently involved in a drowning incident at the coast, followed by inland water bodies. Bath drowning requires intervention for infants less than one year. Swimming alone, or for young children, being in the water unsupervised even for a short time was the most prevalent contributing factor. Mortality and morbidity incidence will be reduced by ensuring engaged supervision around pools and at bath time, improved water safety barriers between the house and pools and dams; and a heightened awareness of buckets and man-made farm water hazards.
CONTRIBUTORSHIP

BAW conceptualised and designed the study, carried out the analysis, drafted the initial manuscript and approved the final manuscript as submitted. KW assisted in the design of the study, carried out quality control of analysis, reviewed and revised the manuscript and approved the final manuscript submitted. JN assisted in the design of the study and approved the final manuscript as submitted. RCF reviewed and revised the manuscript and approved the final manuscript. RMK assisted in conceptualisation of the study, reviewed and revised the manuscript and approved the final manuscript as submitted.

WHERE CHILDREN AND ADOLESCENTS DROWN IN QUEENSLAND: A POPULATION-BASED STUDY

Keywords: drown*, child*, adolescent, incidence, non-fatal drowning

Word count: 5468
ABSTRACT

Object

This retrospective population-based study examined drowning location by the site of immersion for both fatal and non-fatal drowning events in Queensland. Drowning location is not routinely collected, and this study used data linkage to identify drowning sites. The resulting enhanced quality data quantifies drowning incidence for specific locations by geographic region, age group and by severity for the first time.

Design

Linked data were accessed from the continuum of care (pre-hospital, emergency, hospital admission and death data) on fatal and non-fatal drowning episodes in children aged 0-19yrs in Queensland for the years 2002-2008 inclusive.

Results

Drowning locations ranked in order of overall incidence were pools, inland water, coastal water, baths and other man-made water hazards. Swimming pools produced the highest incidence rates (7.31/100,000) for overall drowning events and were more often privately owned pools and in affluent neighbourhoods.

Toddlers 0-4yrs were most at risk around pools (23.94/100,000), and static water bodies such as dams and buckets – the fatality ratios were highest at these two locations for this age group. Children 5-14yrs incurred the lowest incidence rates regardless of drowning location. Adolescents 15-19yrs were more frequently involved in a drowning incident on the coast shoreline, followed by inland dynamic water bodies.
Conclusion

Linked data has resulted in the most comprehensive data collection on drowning location and severity to date for children in the state of Queensland. Most mortality and morbidity could have been prevented by improving water safety through engaged supervision around pools and bath time, and a heightened awareness of buckets and man-made water hazards around the farm home for young children. These data provide a different approach to inform prevention strategies.
ARTICLE SUMMARY

Strengths and Limitations of this study

- Data linkage with case notes provided enhanced detail on non-fatal drowning locations and contributing factors associated with the environment of those locations.
- Incidence related to drowning locations and the effects of age on rates are reported for the first time.
- A breakdown of pool ownership, static and dynamic water bodies, coastal waters, and geographic and socio-economic information provides new perspectives for drowning locations to inform prevention strategies.
- Locations in order of incidence overall were pools, inland water, coastal water, baths and other man-made water hazards.
- Heightened supervision and prevention efforts directed at developmental prevention strategies for all static water hazards close to home are required to reduce the drowning burden for toddlers 0-4yrs who have the largest drowning burden, regardless of the location. Adolescents are more likely to have drowning incidents in coastal water or inland dynamic water.
INTRODUCTION

Approximately every three minutes somewhere in the world a child aged between 0-19yrs drowns. These young people account for almost half of the worldwide annual total deaths, and those under the age of 5yrs are disproportionately affected. These numbers are believed to be underestimated by 39-50% because drowning due to natural disasters, transport incidents and intentional drowning are not included. These data also do not provide a measure of morbidity associated with drowning survival, nor do they provide information about where the drowning occurred. Current data from Queensland for children 0-19yrs established a fatal rate of 1.5/100,000, yet the non-fatal drowning rate was 13.6/100,000 pa. For every fatality ten other children were retrieved from the water and sought medical assistance.

The circumstances leading to drowning can vary widely, and drowning location, age of the child and the child’s activity are inevitably linked. Differences in geographical and cultural factors between high income countries (HIC) and low and middle income countries (LMIC) also exist. In HIC, among children up to the age of one year, most drowning deaths occur in bathtubs. After the first year of life, swimming pools and man-made ponds (dams) or reservoirs are more frequently involved. The World Health Organisation (WHO) recognised that poor quality drowning data have contributed to a neglect of drowning as an important public health issue, and that if prevention strategies are to be successful, they need to be tailored to the local context. This emphasises, the importance of good quality local data such as this which identifies drowning locations.
Currently administrative data bases worldwide collect drowning information according to the International Classification of Diseases (ICD-10)\textsuperscript{16} at only three locations: baths (W65-66) pools (W67-68), bathtubs and natural water (W69-70). All other drowning locations are grouped under “specified” or “unspecified” (W73-74), which hinders injury prevention. Presently there is no international aquatic standard for the classification of water body types which makes comparisons of locations and contributing factors almost impossible between countries. In this study water type has been analysed as five categories to produce data and encourage prevention strategies that may be useful to other countries.

A further challenge to comprehending drowning is the difficulty in obtaining an accurate measure of actual exposure to water. By this we mean using a child-risk measure; that is, children who are likely to access, enter or be near water, rather than children from within a population-based group (some of whom may not necessarily be exposed to water).\textsuperscript{17} An Australian study demonstrated that when explored by actual exposure, drowning risk was under-estimated and was higher than road traffic risk.\textsuperscript{18} This exposure measure reflects temporal fluctuations, lifestyle and regional characteristics, however, obtaining such data is usually done by telephone survey, is labour-intensive, expensive and logistically only possible in High Income Countries (HIC).

Since the seminal work of Pearn and Nixon,\textsuperscript{19} and Pitt et al\textsuperscript{20} exposed unfenced backyard swimming pools and bathtubs as high risk locations,\textsuperscript{12, 21, 22} the 0-4yr old pool immersion rate trebled in Brisbane to 70.2 in 1986,\textsuperscript{23} and then reduced to 20.7 in 2002.\textsuperscript{24} Therefore this is a timely detailed review that encompasses all locations (e.g. pools, dams, bathtubs, creeks and rivers) and an exploration of any contributing factors in the chain of events leading to drowning. These data assist in an understanding of drowning incidents for prevention efforts,
which must take into account child developmental factors, the characteristics of the water body, and the physical and socio-economic environments.\textsuperscript{1,15}

The overarching aims of this paper were to identify locations of drowning events in Queensland children and adolescents, and to quantify the magnitude of fatal and non-fatal drowning at particular sites. Prevention strategies can be adopted for identified drowning sites beyond ICD-10 coding and characteristics associated with reoccurring locations and particular age groups were explored where available. This study fills a crucial gap in reporting locational incidence rates for Queensland children, and presents analyses of fatal and non-fatal drowning location data collected using data linkage. This method achieved the best possible case capture to report all drowning cases as defined internationally.\textsuperscript{25,26} We report for the first time incidence rates for drowning locations which frequently reoccurred in Queensland, along with the severity of events and contributing factors for particular drowning environments.
METHODS

Data were obtained for all drowning episodes in Queensland where medical assistance was sought for children and adolescents aged 0-19yrs inclusive, between 1 January 2002 and 31 December 2008. For simplicity of reading, we will refer to this entire age group as children rather than “children and adolescents”. This paper describes all drowning events, and specific drowning groups (for example those who died), as fatal drowning or non-fatal drowning, as per the internationally agreed definition, and respiratory impairment was considered to have occurred if medical assistance had been sought.

Data custodians, extraction criteria and linkage methods are described elsewhere. However in summary, identified data were manually linked to create a comprehensive dataset across the continuum of care. Cases were included once only if a patient appeared in any of the databases accessed, (patient transfers between hospital facilities were excluded) and were categorised as pre-hospital or emergency department (ED) treatment, hospital admission or death. Additionally, cases were included if the patient died at the scene or subsequently without discharge from hospital. Briefly, data on age, gender, drowning location of event, geographical event location (Accessibility/Remoteness Index of Australia (ARIA) based on event postcode), event time, and day of week were collected. Residential postcode was used to calculate Socioeconomic Index for Areas (SEIFA) and drowning event postcodes were used to determine Index of Relative Socioeconomic Advantage and Disadvantage (IRSAD).

Data on non-fatal drowning locations were obtained from pre-hospital and emergency department case notes, Queensland Injury Surveillance Unit, or ICD-10 codes for hospitalised cases. These notes were also used to obtain information on other circumstances leading to the drowning event.
Descriptive analyses used six categories for drowning locations: 1. Swimming pools (referred to as pools) were considered to be any manufactured structure for swimming in public, private (including wading pools) and commercial spaces. Included in this group were spas where water is not emptied at the end of each use (as opposed to spa baths which are typically emptied after use); 2. Baths were nominated as such and included shower baths and laundry tubs where children were being bathed; 3. Coastal water included beach, surf, and rip currents (where people enter the water from the shoreline) and has been separated from inland water when it was specifically nominated as such in the text. For the purposes of analyses the coastal water category includes ocean and sea where entry to the water was from a boat or jetty, as the number of events were small (6%); 4. Inland dynamic water included creeks, rivers, weirs, streams of water, and flood water; 5. Inland static water is usually naturally occurring water bodies such as lakes, however due to their size, water storage reservoirs (dams) are included as well as those categorised as “inland water bodies” and “large area of water” or “still water” in the data.  6. Locations classified as “other” included manufactured (or man-made) hazards around the home such as buckets, tanks, ornamental ponds, drains and culverts, or animal water storage (such as troughs or dips). These generally involve smaller quantities of water and have been referred to as “other man-made water hazards”.

Private and public pool settings were classified by levels of access. Private settings were considered to be a domestic pool (or water body) for private use of the residents (included single and multi-dwelling pools, wading pools, and outdoor spas). Public pool settings were categorised on two levels of access: Public restricted access: Commercial/municipal operated (or developed) settings where access is restricted by opening or closing times, or to patrons who may have paid for holiday accommodation or to use the facility, (eg. water theme parks,
school pools, hotels, resorts, caravan or holiday parks; and Public unrestricted access: where there is no fencing, or open and close times (eg tidal pools constructed on the beach).

Drowning locations were further collapsed into four categories for the purpose of calculating Incidence Rates (IRs). Inland water includes static and dynamic water, and due to small numbers “other man-made hazards” was grouped with missing. The drowning locations were stratified by Accessibility and Remoteness Index for Australia (ARIA)\textsuperscript{27} and severity (death, admission to hospital, or not admitted).

Fatality ratios were the number of fatal events over the number of non-fatal events. Crude IRs were calculated for each calendar year, using population data from the Australian Bureau of Statistics\textsuperscript{28} and are expressed as per 100,000 per population. Descriptive analyses used data on all drowning events that occurred in Queensland, and IRs were calculated for events among Queensland residents only due to the lack of age-specific population data on non-Queensland residents (for the denominator). Calculation of incidence rates for fatal and non-fatal events was stratified by age, drowning location and severity. Chi square test for trends over time were computed using Centers for Disease Control and Prevention Epi Info\textsuperscript{TM} 7.1.2.0. Relative Risks (RR) and 95% Confidence Intervals were calculated using IBM SPSS Statistics for Windows, Version 22.0. Armonk, NY: IBM Corp released 2013. Descriptive analyses (primarily chi-square tests) were also conducted to determine whether there were variations in characteristics of drowning events. Fisher’s Exact was used where assumptions of chi-square tests were violated.

Ethics and approvals were sought and granted from Children’s Health Services District (Royal Children’s Hospital Human Research Ethics Committee HREC/09/QRCH/38; Royal
Children’s Hospital Institutional Approval; University of Queensland Medical Research Ethics Committee #2009001463; Mater Health Services Human Research Ethics Committee #1446E; and National Coronerial Information System #CF/07/13729 (2007-2010), #CF/10/25057 (2010-2013), #CF/13/19798 (2013-2016). Director General approval was granted through Public Health Application, Queensland Health 16/3/2010 Ref RD002254. Custodian approvals were granted from Royal Life Saving Society Australia, Commission for Children and Young People and Child Guardian, Queensland Ambulance Service.
RESULTS

Descriptive drowning location analyses 0-19yrs

A total of 1299 (120 fatal and 1179 non-fatal) drowning incidents among 0-19yr olds in Queensland occurred between Jan 2002 and December 2008. Drowning location could be identified for 1088 (84%) drowning incidents. Differences in drowning location and age groups are shown in Table 1 ($X^2 = 352.13$ df=8 $p < 0.001$) and indicate that more than half (59%) of all drowning occurred in pools, followed by inland water (13.4%), baths and coastal waters (12.5% respectively), and other man-made water hazards (2.5%). There were significant differences in drowning location by age group. The 0-4yr age group had the highest frequency of drowning with more than two thirds of drowning events occurring in pools (68%), and 18% in baths. For adolescents 10-19yrs more drowning events occurred in coastal water, followed by inland water and pools. The highest fatality ratio (0.69) for 0-19yrs was associated with other man-made water hazards; and a breakdown of these sites showed buckets as being most predominant (32%). Inland water incurred the second highest fatality ratio (dams stand out in this group with a fatality ratio of 2.67), and pools and baths the lowest. Pools generated the lowest fatality ratio indicating that children were more likely to be rescued from a pool and survive the event than any other locations. Males were over-represented in all sites except bathtubs ($X^2 = 13.21$ df=3 $p = 0.004$). More males were involved in events in dynamic water was 1.9:1 rather than static water 1.4:1.

(%) within location; †Fatality ratio = number of fatal events/number of non-fatal events; ‡80 pools were not able to be identified as public or private; np = not publishable due to small numbers. Data on frequency of Other man-made water hazards are presented in this table but for analyses this category was collapsed into missing. † Drowning location was not able to be identified for 211 drowning events (16%).

Eighty eight percent of pools were identified as being operated for public or private use. The frequency of occurrence of particular drowning sites is presented in Table 2 and the top three sites for each age group are ranked for fatal and non-fatal events. As in table 1, the majority of pool drowning events (n=367 57%) occurred in privately owned pools and a further 161 (25%) were in public (commercially operated) pools where access was restricted to patrons.

There were no fatalities at public unrestricted access pools. Most children who got into difficulty in pools (60%) were in the water rather having fallen in at the time of the incident. However, the inverse was true for 0-4yrs olds as they were most likely (85%) to have fallen in ($X^2=15.88$ df=4 $p<0.01$). There were 68 incidents that could be identified as inland static, and 78 as dynamic water incidents.

Note for sub-categories: Pools (private, restricted access or unrestricted access); Inland water (static or dynamic); Coast (entry to water shoreline or offshore); np = not publishable due to small numbers

**Remoteness:** Figure 1 shows the proportion of drowning events that occurred at specific sites in the state of Queensland by remoteness (ARIA). Pools were the most frequent drowning location for all geographic regions, with the majority occurring in Major Cities (33%), Regional (24%) and Remote (2%) ($X^2=28.23$ df=6 p<0.001). All other drowning occurred at sites in similar proportions across the geographic regions.
Socio-economic status: Drowning locations varied between areas in the highest 50% of IRSAD (decile 6-10 indicating a relative advantage) compared to those in the lower 50% (decile 1-5 indicating relative disadvantage) ($X^2=22.61$ df=3 $p<0.001$). The highest frequency of drowning locations in most advantaged areas were pools (64%), followed by baths (13%) and coastal waters (12%). In areas with a relative lack of advantage twice as many drowning events occurred in inland water (22% vs 11%) and other man-made hazards (4% vs 2%) than areas of advantage. Disadvantaged areas also incurred higher proportions of fatal drowning events than disadvantaged areas (14% vs 7%), and higher proportions of fatal drowning events compared with non-fatal events (43% vs 28%). ($X^2=14.717$ df=1 $p<0.001$).

Overall drowning location incidence rates 0-19y years

There were 1179 Queensland residents involved in drowning events and 981 (83%) where a drowning location was identified (Figure 2).

[Insert Figure 2]

Overall, the highest drowning incidence rates for 0-19yr olds over the study period were in pools. This was followed by inland water, coastal water, baths and man-made water hazards.

*p<0.05; **p<0.01; ***p<0.001; Increases (↑); decreases (↓), or no change (←→) in drowning incidence over time; † Not Admitted = non-fatal cases that did not require hospitalisation but were treated in emergency department or attended by ambulance with no further treatment; ‡ Reference category females.

Trends over time: Pools had the highest IRs for all types of drowning events (Table 3). Total drowning rates (fatal and non-fatal combined) for 0-19yr olds significantly increased over the study period for pools (69%), inland water (67%), and in coastal waters (63%), whereas there were small (non-significant) decreases in rates for bath and man-made water locations. Non-fatal drowning events were a significant proportion of these increases - pools (87%), inland water (85%) and the coast (63%). There were no significant changes over time in fatal rates for any location.

Gender: The male to female ratio for all drowning events where location could be identified was 1.5:1 which varied by location ($X^2=13.21$ df=3 p=0.004). Males had a greater risk of drowning than females at any location, but particularly pools and inland water. The only exception was baths where a risk of drowning was 22% lower in males than females though this was not significant (RR=0.78 0.56-1.10).
Location by age group and severity

Trends over time: There were no significant changes over the seven years in fatal rates at any of the locations in any age group. Where total incidence rates increased this was primarily due to increases in non-fatal drowning events (Table 4). Pool drowning rates increased over time in every age group except for those aged less than 12 months, however the increases were significant in children 0-4yrs, 1-4yrs and 5-9yrs. Increased rates were seen in inland water drowning for 10-14yr non-fatal drowning, and coastal drowning in 5-9yr olds. For children over 2yrs bath drowning is a rare event. The highest percentage (74%) of unknown locations was in the 0-4yr age group.

Analyses for the separate locations stratified by age and severity are shown in Figure 3 and Table 5. Information on contributing factors where they were able to be identified is presented in the following text.
**Pool Drowning:** Swimming pools (Figure 3) incurred high drowning rates in the 1-4yr age group for fatalities, admissions, and non-admissions than any of the other age groups. The highest rates of pool drowning occurred in children aged one, two and 3yrs for total drowning events, hospital admissions and fatal events. Two year olds were the most vulnerable in terms of risk of pool drowning (IR=37.34).

RR† - Relative Risk reference group 5-19yrs; RR‡ - Relative Risk reference group Fatal (non-fatal is any drowning event – pre-hospital and admitted); IR – Incidence Rates quoted per 100,000 population per annum; np = not publishable due to small numbers.
**Inland Water:** Fatal drowning occurred at this location across all age groups, *(Figure 3)* however no infant <1yr fatally drowned in inland water bodies. Dams were the most common location in this category for the 1-4yr age group. Toddlers aged 1-4yrs were 2.7 times more likely to drown than their counterparts aged 5-19yrs in bodies of inland water *(Table 5).* Admission rates for inland drowning were highest for 1-4yrs (IR=2.23) and <1.0 for all other ages.

**Bath Drowning:** Bath drowning was more frequent and severe in children under five years *(Figure 3).* The male to female ratio for bath drowning was the same for <1yr and 2-4yrs, but the bath drowning rate was 1.1 times higher for females than males aged 1yr old, and seven times higher for females 5-19yrs (compared with males) *(Table 5).* Ranked fourth in drowning locations overall, bath drowning incidence was the greatest for infants aged 0-1yr. The risk of a bathtub drowning event for an infant aged <1yr is 143 times that of children 5-19yrs.

Examination of case notes showed that the majority (67%) of bath drowning events occurred when there was no supervisor in the room (the child was knowingly left alone in the water even for a short time ranging from 1s to 30mins). Seven percent were left with a sibling (aged between 3-5yrs) where the sibling either did not respond to, or contributed to the drowning in some way, or alternatively alerted the parent (usually that the water was overflowing). A small percentage (5%) was the result of a seizure or intentional harm. None of the 18 cases who had direct supervision were fatal and all but one were aged <1yr.
**Coastal Drowning:** Fatalities from drowning at the coast were rare (IR<1) but occurred in all age groups. There were no coastal drowning fatalities for infants aged less than 1yr (Figure 3). Drowning in coastal waters incurred the lowest total drowning rates for all children 0-19yrs. Admission rates were highest for 1-4yrs, and were <1.0 for all other age brackets. Almost half of fatal coastal events were related to offshore watercraft, swimming alone or at night, or in rough unpatrolled surf. Almost half of all fatal offshore watercraft victims were not wearing a life jacket. Risk of a coastal drowning event was 16% lower in younger children 1-4yrs than older children 5-19yrs, but this was not significant (95% CI=0.52-1.35) (Table 5).

**Other man-made water hazards:** (data not shown due to small numbers). This category had the lowest numbers of drowning events of all, yet the highest proportion of fatalities (41%). All fatalities occurred among 0-4yrs. There were no drowning events (fatal or non-fatal) in 5-9yrs, or 10-14yrs and non-fatal events were rare in 15-19yrs. Incidence was highest incidence in children 0-4yrs (IR=3.18) and 96% of all cases were in this age group. Admission rates for <1yr and 1-4yrs were approximately equal (IR=0.53 and IR=0.54). The majority of these locations involved static water, and buckets were the most common drowning danger (33%). Hazards such as ornamental ponds, tanks, stock troughs and stock dips presented the greatest risks for toddler drowning especially for those under one year (IR=1.34) and the risk of drowning in such water hazards was 78 times that of older children 5-19yrs (RR=78.50 95%CI 9.171-671.90). Males were twice as likely as females to drown in these types of water bodies, but this was not significant.
DISCUSSION

Drowning locations ranked in order of overall incidence were pools, inland water, coastal water, baths and lastly other man-made water hazards. The magnitude of drowning at these sites was much greater in Queensland than previously reported for the rest of Australia or the USA.²⁹-⁻³²

Previous research indicates that young children aged 0-4yrs had a seven-fold risk of a drowning event over 5-19yr olds,⁶ signifying that the high risks for drowning associated with the early developmental years need to be examined in the context of pools, baths, and inland water - particularly water storage dams and other man-made water hazards close to the home. Mortality case series have previously provided the only data on hazardous locations such as dams or buckets,³³ ³⁴-⁻³⁷ whereas, these detailed locations provide insights for national hospitalisation data²² which lacks location detail beyond ICD-10 coding of pools, baths and natural water. Coding for more than one quarter of the 0-4yr cohort was “unspecified” and yet this age group constitutes 43% of the total all-age drowning hospitalisation in Australia.³² The detail contained in this non-fatal data points to locations around the home that are not unique to Queensland, and are eminently preventable at a national level with appropriate interventions.

The discussion which follows is presented in the context of location (or water type), the predominant age of the child affected, and any prevalent contributing factors. The results reinforce the necessity for better drowning location definitions (an aquatic standard) for the classification of water body types in coded data enabling prevention strategies to be targeted by drowning location as well as geographic regions. Such multi-level approaches can target
an appropriate audience for the age group at risk, and promote specific interventions observed
to have promising outcomes.10 38 39

Pools

Overall, more than half of all Queensland child drowning occurred in pools and
predominantly among males. Encouraging signs of fatality prevention are that the swimming
pool fatality rate is much lower than reported in 1976 (IR=0.65 vs IR=22.55),40 and pools
incurred the lowest fatality ratio of all sites. However, the highest admission rates, and
significant increases in non-fatal pool drowning rates over the reporting period, along with
higher rates than previously reported in 1976 (IR=9.49 vs IR=6.2)40, indicate the potential for
morbidity and further fatalities10 and highlight that there is no room for complacency if this
significant burden is to be reduced. Pool drowning occurs predominantly in privately owned
pools, which are more often than not located in areas of relative high socioeconomic
advantage. It occurs more often in the city, but also in inner and outer regional areas as well
as remote areas across Queensland.

Pool density has been shown to affect drowning20 41 42 although the methods to calculate it
differ between pools/population-at-risk and pools/number of dwellings. An estimate of
311,0001 pools and spas registered in Queensland homes43 per 1,660,750 dwellings44 gives
density ratio of 1:5 which is similar to an earlier Brisbane City study.20 To some extent this
high density of pools would explain the over-representation of this location in drowning
episodes, however, this higher exposure will also require consolidation of political will and
public acceptance for ever-strengthening interventions to be implemented. The Queensland

1 *(G Hemmings, A/Principal Advisor DLGP, personal email communication, March 28, 2012)
Pool Registry (operating since 2010) is anticipated to not only confirm the number of pools in Queensland, but also verify the presence of pool fencing which complies with current legislation. More importantly, with an aging stock of pools in Queensland, ensuring that fences and self-closing gates are maintained and operating is a priority.\textsuperscript{45}

It is equally important to prevent young children from getting into the pool alone, but also to protect them while they are in the water. The majority of children got into difficulty while they were known to be in or around water however, 0-4yr olds were most likely to have fallen in. Pool fencing was mandated in Queensland in 1991 and has been shown to be an effective drowning countermeasure for such lapses in supervision of young children.\textsuperscript{20,46} Over the long term, pool fatality in this age group has reduced in Queensland and this has been linked to ever-strengthening legislation implementing standards related to pool fencing.\textsuperscript{47,48} Regulatory control by individual local councils from 1992 led to inconsistencies in enforcement so it is difficult to say definitively that this has reduced fatality on its own, however as the only intervention promoted consistently over the time this is a positive sign toward reducing drowning in this age group.

Obligatory CPR courses for all registered pool owners could provide an opportunity to append other pool safety information about pool toys and flotation devices; and the necessity for close, constant and visual supervision.\textsuperscript{49,50} This is particularly critical for the vulnerable ages 1-3yrs. In this study dimensions of supervision ranged from “direct” (constant visual where physical proximity to the child allowed a quick response) to “indirect” supervision (where the supervisor knows the child is in or near water but is unable to take immediate protective action).\textsuperscript{51} Common risk factors were reliance on siblings as caregivers, or a misguided belief that carers would hear if trouble occurred. In the majority of these lapses
(over 64%) caregivers knowingly left the child in or near water for just a short time to tend to
laundry, food preparation or the phone.

The older age groups incurred the least pool immersions and it is not clear why they were
involved in fewer events, but may be related to better swim ability, some level of supervision
and/or a developing concept of water safety. Nonetheless, this was the location with the
highest frequency for 5-9yr olds, leaving no room for complacency.

**Inland water**

Ranked second as a drowning location overall, this was the leading location for fatalities in
children 5-19yrs. In younger children 1-4yrs more than half (55%) of drowning locations
were dams with an overwhelming fatality ratio of 2.66. In rural settings a safe fenced house
yard/play area is the best way to prevent young children from wandering alone long
distances\(^{33}\) to water hazards that they may have visited regularly. For adolescents 10-19yrs
these settings more often involved dynamic water and was more frequently chosen for
recreation than pools. Inland water settings have been targeted nationally\(^{52}\) and this may go
some way to reducing the significant increase in drowning at this type of location. Behaviour
change interventions which tackle common risk factors such as over- or under-estimating
ability or current strength; swimming alone or at night, or after consuming alcohol.\(^{53}\)\(^{54}\) These
kinds of water settings were more often found in areas of relative low socioeconomic
advantage.

**Baths**
Hospital admission following a bath drowning was second only to pool drowning in children 0-19yrs. and may be related to the young age of most bath immersions. A further breakdown of ages within the 0-4yr group indicated engaged direct supervision as lacking in the bathroom for infants <1yr. Although bathtubs ranked as the fourth location in overall drowning, a very high risk was indicated for infants <1yr (143 times 5-19yr olds). Bathtub drowning interventions are best targeted at parents of very young children as immersions are unusual above 2yrs. Parents and carers should be reminded to never leave young children alone in the bath (even for short periods) or in the care of a sibling. Baths were the sole location where significantly more females than males had drowning events. The other age group of concern for bath drowning is adolescents 15-19yrs where intent and the involvement of other substance use played a role.

Coastal water

Non-fatal drowning rates increased over the study period and the coastal shoreline was the second most frequent location for intervention activities for 5-9yrs. Unfortunately, it is not always recorded if coastal drowning events were at beaches patrolled by lifeguards, albeit a sound drowning prevention intervention to address the significantly increasing burden. It is law that children 1-12yrs require a life jacket (PFD) when in small boats. Small watercraft incidents offshore resulting in fatality show that children not wearing life jackets can and do drown. Water recreation incidents for adolescents 15-19yrs at the surf beach involved rip currents, exhaustion and alcohol. Interventions and risk factors suggested were similar for Inland water drowning (see above).

Other man-made water hazards
These more unusual water bodies produced the highest fatality ratio and mostly occurred in children 0-4yrs (96%). Strengthened efforts are required to educate new parents that buckets left partly filled after use resulted in one third (32%) of drowning events. They are a lesser known but universal threat as are man-made water hazards such as troughs, in-ground tanks, and drains or culverts. There is scope to mitigate access at the time these water bodies are created. These were more common in areas of relatively low socioeconomics generally in line with more rural settings.

Strengths and limitations: This is the first study on drowning location to comprehensively utilise linked data across the continuum of care (pre-hospital to fatality), and effectively map the ‘patient journey’ from the moment of retrieval from the water to definitive care. Drowning is a process which is the outcome of a chain of events, and data that capture patterns within that chain of events has an inherent value. The value in collecting text narratives is validated by the previously unexplored magnitude of non-fatal drowning locations that frequently reoccur. Data linkage limitations have been published previously.

This linked data is a major strength of this study and allowed identification of detailed information on drowning location. A substantial proportion of data on drowning location were obtained from case notes prepared by paramedics (eARF) who attended the scene, or text entered in the “presenting complaint” field in the emergency department. This was true even for cases resulting in hospitalisation following the drowning event, as information on these events is limited by the available ICD10 codes to the following categories: bathtub (W65-W66), swimming pool (W6-68), natural water (W69-70, with no differentiation between lake, open sea, river and stream); Other specified drowning and submersion (W73); and unspecified drowning locations (W71, a very frequently occurring code indicating it is
used as a dump code). Including the pre-hospital and emergency case notes allowed calculation of incidence rates and analyses at a much more detailed level than has previously published. The utility of the consequent linked data is great, and also allowed identification of factors that contributed to the drowning event such as supervision, swimming alone and similar other risk factors. Data on supervision and contributing factors were not analysed in detail in this paper but are planned for the future.

The authors acknowledge that coastal drowning events may be underestimated where it has been categorised as “large area of water” or “natural water”. These, along with “natural still water” have been categorised as inland static water. Age-specific population data used to calculate rates for immersion sites may underestimate risk of drowning, however water exposure data and pool data were not available for Queensland. Further work is required in improving the collection and description of aquatic locations. It may be that some parents sought medical care for their children as a precautionary measure after the event, and this is noted when known.

In 2010 further legislation that post-dates these data introduced a register in Queensland where pool owners are obligated to register their pools, and ensure pool fencing complies with Australian standards before sale or rental of the property. Owners who don’t sell or rent had a five year window to ensure that their pool fencing complied. Certification requires updating every two years. The register utilises hospital presentation data, and any pool where a child had a drowning event and seeks medical assistance is investigated for contributing causes. We look forward to findings of these inspections to provide contributing factors to morbidity and improved fencing compliance.
CONCLUSION

This is the first study in Australia to link data for drowning events and explore the differences between fatal and non-fatal drowning locations by incidence, age and severity. This enhanced quality data have identified target populations, socio-economic groups, geographic regions along with contributing factors specifically related to drowning locations in Queensland. This is a different perspective to inform injury prevention strategies.

Swimming pools yielded the highest incidence rates for overall drowning events and pose the largest burden across all age groups. Swimming pools dominate the drowning burden for 0-4yrs and produced the most fatalities, admissions and affect more age groups than any other location. Older children were more frequently involved in a drowning incident at the coast, followed by inland water bodies. Bath drowning requires intervention for infants less than one year. Swimming alone, or for young children, being in the water unsupervised even for a short time was the most prevalent contributing factor. Mortality and morbidity incidence will be reduced by ensuring engaged supervision around pools and at bath time, improved water safety barriers between the house and pools and dams; and a heightened awareness of buckets and man-made farm water hazards.
CONTRIBUTORSHIP

BAW conceptualised and designed the study, carried out the analysis, drafted the initial manuscript and approved the final manuscript as submitted. KW assisted in the design of the study, carried out quality control of analysis, reviewed and revised the manuscript and approved the final manuscript submitted. JN assisted in the design of the study and approved the final manuscript as submitted. RCF assisted in the design of the study, reviewed and revised the manuscript and approved the final manuscript. RMK assisted in conceptualisation of the study, reviewed and revised the manuscript and approved the final manuscript as submitted.
