The Environmental footprint of morphine: a life cycle assessment from opium poppy farming to the packaged drug

Scott McAlister, Yanjun Ou, Elise Neff, Karen Hapgood, David Story, Philip Mealey, Forbes McGain

ABSTRACT

Objective: To examine the environmental life cycle from poppy farming through to production of 100 mg in 100 mL of intravenous morphine (standard infusion bag).

Settings: Australian opium poppy farms, and facilities for pelleting, manufacturing morphine, and sterilising and packaging bags of morphine.

Main outcome measures: The environmental effects (eg, CO₂ equivalent (‘CO₂ e’) emissions and water use) of producing 100 mg of morphine. All aspects of morphine production from poppy farming, pelleting, bulk morphine manufacture through to final formulation. Industry-sourced and inventory-sourced databases were used for most inputs.

Results: Morphine sulfate (100 mg in 100 mL) had a climate change effect of 204 g CO₂ e (95% CI 189 to 280 g CO₂ e), approximating the CO₂ e emissions of driving an average car 1 km. Water use was 7.8 L (95% CI 6.7 to 9.0 L), primarily stemming from farming (6.7 L). All other environmental effects were minor and several orders of magnitude less than CO₂ e emissions and water use. Almost 90% of CO₂ e emissions occurred during the final stages of 100 mg of morphine manufacture. Morphine’s packaging contributed 95 g CO₂ e, which accounted for 46% of the total CO₂ e (95% CI 82 to 155 g CO₂ e). Mixing, filling and sterilisation of 100 mg morphine bags added a further 86 g CO₂ e, which accounted for 42% (95% CI 80 to 92 g CO₂ e). Poppy farming (6 g CO₂ e, 3%), pelleting and manufacturing (18 g CO₂ e, 9%) made smaller contributions to CO₂ e emissions.

Conclusions: The environmental effects of growing opium poppies and manufacturing bulk morphine were small. The final stages of morphine production, particularly sterilisation and packaging, contributed to almost 90% of morphine’s carbon footprint. Focused measures to improve the energy efficiency and sources for drug sterilisation and packaging could be explored as these are relevant to all drugs. Comparisons of the environmental effects of the production of other drugs and between oral and intravenous preparations are required.

INTRODUCTION

Healthcare’s environmental effects are receiving increasing attention.1 2 Life cycle assessment (LCA) is a scientific method used to calculate the entire ‘cradle-to-grave’ environmental effects (‘footprint’) of a product or process.3 LCA has been used to estimate healthcare’s entire ‘carbon footprint’, which has been found to be responsible for 3% and 9.8% of the 2013 CO₂ equivalent (‘CO₂ e’) emissions of England4 and the USA5.
respectively. The USA spends almost twice as much on healthcare (17.1%) as a proportion of gross domestic product (GDP) as the UK (9.1%). Australian healthcare CO₂ e emissions are unknown, although healthcare costs are similar to those of the UK (9.4% of GDP). Furthermore, Australian clinical practice broadly reflects that in the UK, Europe and Canada, though it is less financially costly than healthcare in the USA. In 2012, the production of all pharmaceuticals used by the National Health Service (NHS) of England contributed >20% of the total CO₂ e emissions (ie, all purchasing, energy use and transport) arising from the NHS’s activities. Owing to this environmental footprint, the UK NHS Sustainable Development Unit developed a guideline to perform pharmaceutical LCAs.

LCAs exist for whole operations and individual devices, but LCAs of drugs are rarely publicly available due primarily to the proprietary nature of drug synthesis. Some published ‘in-house’ (commercial in confidence) LCAs, however, have been performed by drug companies. Most published LCAs of pharmaceuticals examine only the technical aspects of drug manufacture. How drug ingredients are put together, however, is less clear, and industry LCA publications cannot be verified. A large majority of a drug’s environmental effects are due to the manufacture of the actual drug that doctors prescribe, compared with the production of the precursor ingredients. It appears that the production of all drugs collectively has a very large carbon footprint, although individual drug information is lacking. The primary aim of this study was, thus, to know further about the entire environmental effects of a drug as used by clinicians. We chose to study morphine as it was a commonly used drug, known worldwide, that Australia produced in considerable quantities, and that could be studied with the collaboration of supportive pharmaceutical companies.

Morphine is on the list of the WHO Essential Medicines and “remains the most widely used opiate for the management of pain.” In 2013, the global legal production of the three most common opiates in descending order were morphine 523 tonnes, codeine 361 tonnes and oxycodone 261 tonnes. There are four natural opiates derived from the opium poppy: morphine and codeine, as well as thebaine and oripavine (parent compounds to oxycodone and buprenorphine, respectively). Direct chemical synthesis of morphine has proved difficult and production via poppies remains the only commercial synthesis route. Australia produces ~50% of the global supply of licit opium poppy alkaloids (plant-based nitrogen-containing organic compounds, such as morphine), including 37% of the licit morphine, exporting to Europe, the UK and elsewhere.

We aimed to quantify all of morphine’s environmental effects (CO₂ e emissions=CO₂eq, water use, aquatic and terrestrial pollution, etc), from opium poppy cultivation, production of morphine sulfate and through to intravenous formulation, including packaging. Kg CO₂eq is the standard unit for measuring carbon footprints and expresses the global warming potential of different greenhouse gases in ‘CO₂ e’ that would create the same amount of warming.

Intravenous morphine in Australia is most commonly prepared in 10 mg glass ampoules for bolus administration and as 100 mg in 100 mL bags for infusions and patient-controlled analgesia. We were interested in the environmental effects of both intravenous preparations. We undertook a ‘cradle-to-gate’ LCA of morphine with GSK (Glaxo Smith Kline) and Baxter, both large, international pharmaceutical companies. Three companies in Australia produced 37% of the world’s licit morphine, the majority of which (>25%) was produced by GSK. Baxter did not manufacture morphine, but was the only company that packaged and sterilised the 100 mg morphine into 100 mL bags in Australia. A cradle-to-gate LCA examines a product’s life cycle from the beginning to its exit from the ‘factory gate’ and does not include the syringes, intravenous fluid-giving sets, etc, used by a clinician when administering the intravenous morphine to the patient. Sun Pharmaceutical Industries purchased GSK’s opiate production business in 2015. Since all data were obtained from GSK, references are made to ‘GSK’ hereafter.

METHODS

Ethical approval for this LCA was granted by the Western Health Ethics Committee (QA 2014.10), Melbourne, Australia. The study was undertaken from April 2014 to April 2016. Funding was obtained from the Australian and New Zealand College of Anaesthetists and Monash University. Researchers had access to all data, which were obtained from (1) Tasmanian opium poppy farms and GSK’s poppy pelletising facility, (2) GSK’s opiate manufacturing facility in Victoria and (3) Baxter’s intravenous manufacturing facility in Sydney. No patients were involved in this study. The research questions and outcome measures were developed entirely by the investigators.

LCA is a scientific method that provides environmental modelling of the entire life of a product or process. In 1991, the Society for Environmental Toxicology and Chemistry defined the six components to be analysed in an LCA: (1) raw material acquisition; (2) processing and manufacturing; (3) distribution and transportation; (4) use, reuse and maintenance; (5) recycling and (6) waste management. The International Organization for Standardization (ISO) has standardised how LCAs should be performed (the ISO 14040 series). We performed a process-based LCA, that is, the environmental effect was calculated for each product or service in the life cycle based on measured inputs, such as electricity or chemical usage.

Following the ISO 14040 Standards, an LCA must have a System Boundary (figure 1), a clear a priori definition
of what is and what is not to be included in the analysis.29 Following these standards,29 all existent infrastructure required for morphine’s production (such as plant equipment) lay external to the System Boundary. In contrast, anything that was used in the manufacture, transport or delivery of morphine was examined; that is, (1) raw material (plant-based products, eg, cellulose) extraction, (2) chemical reactions and solvents, (3) energy use, (4) transport of all these agents and (5) associated packaging and waste.

An LCA uses different types of data for modelling. Some data are directly collected, for example, the amount of electricity used by the morphine-manufacturing facility. Most LCA data, however, are not directly measured, but obtained from life cycle inventories calculated from many production sites as directly measuring all data would make most LCAs unviable. One example is all the inputs and outputs associated with the production of 1 kWh of electricity from brown coal mining through to transmission. In this study, a hierarchy of data sources has been used in the following descending order: (1) data collected from poppy growers, GSK and Baxter Australia, (2) the Australian LCI database30 and (3) EcoInvent V3 (European data).31 Modelling was performed using the SimaPro 8 LCA software (PRé Consultants, Amersfoort, the Netherlands).

In process-based LCA, ‘allocation’ is required when a single process produces multiple outputs, so that environmental effects can be allocated to each output. ISO 14044 (4.3.4.2 Allocation procedure)29 gives a stepwise process in dealing with multi-output processes: (1) avoid allocation through dividing processes, (2) allocate based

![Figure 1](https://www.bmjopen.bmj.com/content/6/6/e001332 figura1.png)

**Figure 1** System Boundary for morphine production. LCA, life cycle assessment.
on physical relationships such as mass or (3) allocate by other relationships, such as financial value.

There are two multi-output processes in morphine’s manufacture by GSK: pelleting, which produces poppy straw pellets (for opiates) and poppy seeds (for food), and the concentrated poppy straw process, which produces morphine, codeine, oripavine and thebaine. We were unable to avoid allocation by dividing the processes (a single process provides poppy straw and seeds). Furthermore, a physical relationship (mass) did not capture the economic reality of why poppies were grown. Farmers grew poppies for the opioid content, not the poppy seeds—pharmaceutical companies were not about to grow opium poppies so that they could supply the food market. Therefore, we followed step 3 of ISO 14044 and allocated based on the financial value.29

The environmental effects were allocated based on the market value price (ie, price/kg multiplied by kg mass) for each output. For each process, we calculated a weighted average based on annual production data from 2012 and 2013, and this was modelled in SimaPro.

All modelling included an uncertainty value expressed as a lognormal probability distribution derived from a qualitative scoring system (the Pedigree Matrix).32 Each input has uncertainty attributed to it from the qualitative scoring system derived from the data’s reliability, completeness and temporal and geographical proximity, with these uncertainties being included in all major LCA databases. A final 95% CI for a process is achieved based on the random sampling anywhere within the 95% CIs for all inputs (Monte Carlo analysis). A Monte Carlo analysis by the LCA modelling software includes at least 1000 ‘runs’ of random samples to reduce the chance of unusual results.

Impact assessment was performed using the ReCiPe LCIA (Life Cycle Impact Assessment) method.33 The following impact categories (and their units) were calculated: climate change (g CO2 eq); ozone depletion (kg trichlorofluoromethane (CFC-11) equivalents); photochemical oxidant (smog) formation (kg non-methane volatile organic compound equivalents); and human, terrestrial and marine ecotoxicity (kg 1,4-dichlorobenzene equivalents).

Normalisation is a method used to indicate the relative importance of an impact category; we ‘normalised’ the results for each impact category (ie, divided our results by an average Australian’s per capita emissions in each category) as per ISO 14044.29 Normalisation takes into account potential effects from national electricity and fuel mixes. Per capita, Australia is a high emitter of CO2eq, which may appear to reduce the environmental impacts of morphine production. Nevertheless, morphine made in the UK, for example, would have a lesser climate change impact (CO2eq) than that made in Australia due to the different electricity mix. A lesser environmental impact, being compared to a lesser per capita emission, may be comparable to the normalisation percentage of Australia.

**Farming, pelleting and transport**

Data for poppy cultivation and straw pelleting were collected from the GSK Head of Crop Supply. We obtained all data regarding opium poppy fertiliser, insecticides, herbicides, tractor diesel use and irrigation water use for a 2-year period (2012 and 2013). Road and domestic shipping of poppy straw and international shipping of chemicals to the farms were also examined.

**Bulk morphine manufacture**

Data from the manufacturing plant were obtained from several sources. Production of concentrated poppy straw (CPS) was a continuous process, but further manufacture of the final morphine sulfate was by a batch process. If a chemical was used only in the CPS process, then the ‘Raw Material Spreadsheet’ that records entire monthly chemical usage was used. If a chemical was used in other processes, then data from a system used to control and monitor process streams were used. Details of use/reuse of chemicals (including solvents) and water were obtained, including waste and sewage data.

For technical morphine (ie, 95% morphine by dry weight) and morphine sulfate, exact chemical usage was obtained through individual batch sheets, with these recording all operating parameters, including input chemicals, and operating time and temperature. We randomly selected 30 batch sheets from each year of 2012 and 2013, and average values were calculated.

The GSK manufacturing facility monitored the electricity usage of individual equipment via an ‘Energy Matrix’ computer system. The final morphine production step, however, was not connected to the Energy Matrix. We, thus, calculated associated electricity use by multiplying the associated equipment’s energy ratings with the respective operating times obtained from the batch sheets.

**Mixing, filling, sterilisation and packaging**

The Baxter Sydney factory did not manufacture morphine, but rather received bulk morphine sulfate, which was packaged as 100 mg morphine into polyvinylchloride (PVC) plastic bags with 100 mL sterile 0.9% saline. In 2015, Baxter Australia sterilised ~32 000 bags of morphine for intravenous use. Each PVC bag was packaged in high-density polyethylene (HDPE) plastic overpouch bags and cardboard boxes. Box 1 indicates the routine stages of production of morphine from these sources. We were unable to obtain data regarding the environmental effects of 10 mg glass ampoules despite repeated requests to the manufacturers.

Baxter Australia purchased bulk morphine that did not require further chemical modification. Owing to contractual arrangements, the morphine received by Baxter Australia was not directly sourced from GSK. (GSK did supply Baxter with bulk morphine previously.) We had access to all aspects of the preparation of 100 mg morphine in 100 mL bags by Baxter. Packaging for 100 mg morphine required 16 g of PVC as the
packaging associated with such 10 mg morphine ampoules at Footscray Hospital.

RESULTS

We completed a ‘cradle-to-gate’ LCA of morphine sulfate from opium poppy farming (fertilisers, insecticides and irrigation), poppy pelletisation, GSK’s bulk morphine manufacture and Baxter’s sterilisation and packaging. The environmental effects of producing 100 mg of morphine were compared with a commonly identified activity (burning 1 L of petrol). For all but CO$_2$ e emissions, ozone depletion and water use, burning 1 L of petrol had environmental effects which were several orders of magnitude greater than those of producing 100 mg of morphine. We have focused on CO$_2$ e emissions and provide further information regarding other environmental impacts in online supplementary table S1 with associated documentation. Only the details of CO$_2$ e emissions are considered further.

The climate change effects of producing 100 mg of morphine were 204 g of CO$_2$ (95% CI 186 to 264 g of CO$_2$). Figure 2 shows the breakdown in the effects of climate change (CO$_2$ e emissions) according to morphine’s life cycle stages. Production of 100 mg of bulk morphine (ie, from poppy farming and pelletising to GSK’s bulk morphine) produced 24 g of CO$_2$ (12% of the total), while filling, mixing, sterilisation and packaging produced 180 g of CO$_2$ (88% of the total). The average Australian is responsible for 18.5 tonnes of CO$_2$ per annum,$^{34}$ indicating that this 100 mg of morphine producing 204 g of CO$_2$ is ~0.4% of the daily per capita...
Australian CO₂ e emissions and equivalent to the CO₂ e emissions of driving an average car ∼1 km.  

**Farming, pelleting and transport**

The entire contribution from poppy farming, pelleting and bulk morphine manufacturing was 24 g of CO₂, which accounts for 12% of the total CO₂ e, (95% CI 22 to 27 g CO₂ e). Poppy farming contributed 6 g of CO₂, stemming particularly from nitrogen and phosphorus fertilisers (3 g of CO₂) and farm machinery (2 g of CO₂). Diesel for farm machinery was much more important to CO₂ e emissions than all other aspects of transport combined. Road, domestic shipping of poppy straw and international shipping of chemicals to the manufacturing facility contributed less than 0.2 g of CO₂. Pelletising added only 0.5 g of CO₂.

**Bulk morphine manufacture**

The GSK morphine-manufacturing plant added 18 g of CO₂, arising mainly from the electricity (9 g of CO₂) and chemicals (solvents, acids and alkalis and filter aids; 4 g of CO₂) used. By process at the GSK factory, the CO₂ e emissions from the production of concentrated poppy straw predominated (10 g of CO₂), followed by morphine sulfate (4 g of CO₂) and technical morphine (ie, 95% morphine by dry weight) production (4 g of CO₂).

**Mixing, filling, sterilisation and packaging**

The final processes of morphine production (mixing, filling, sterilising and packaging) at Baxter’s Sydney manufacturing plant contributed 181/205 g CO₂ (88%) to 100 mg morphine’s total CO₂ footprint. Mixing (26 g of CO₂), filling (16 g of CO₂) and sterilisation (43 g of CO₂) of 100 mg of morphine bags added 85 g of CO₂, which is 42% of the total CO₂e (95% CI 80 to 92 g CO₂ eq). Morphine’s packaging contributed the largest amount to CO₂ e emissions for any process, 95 g of CO₂, which is 46% of the total (95% CI 82 to 155 g CO₂ e).

If Baxter’s Sydney factory had used natural gas for heating/sterilising and the New South Wales’ electricity grid for other energy requirements instead of gas trigeneration, the CO₂ e emissions for a 100 mg morphine pouch would have been ∼228 g of CO₂. Packaging for 100 mg morphine required 16 g of PVC as the enclosing plastic bag, a 9 g polyethylene overwrapping pouch and a 9 g cardboard box.

**Packaging associated with a 10 mg morphine glass ampoule**

We estimated that the packaging masses associated with 10 mg morphine ampoules were: one glass ampoule (1.9 g), one plastic polypropylene tray (0.6 g) and one cardboard and paper (1.8 g). In looking at the environmental effects of the packaging, this contributed 6.9 g of CO₂, that is, more than twice the CO₂ e emissions of the 10 mg bulk morphine (2.4 g of CO₂ or 1/10th of 24 g of CO₂ from 100 mg of bulk morphine) itself.

**DISCUSSION**

We examined the environmental effects of producing morphine, from opium poppy cultivation through to the final packaged drug. The environmental effect of producing 100 mg of morphine was 204 g CO₂ e for climate change. Other environmental effects examined were considerably smaller than burning 1 L of petrol for car transport, except for ozone depletion, though even this was just 0.04% of the ozone-depleting effects arising from an average Australian’s daily activity (see online supplementary table S1). Importantly, almost 90% of morphine’s carbon footprint arose from the final stages of production; steam sterilisation added 20% to the total, while packaging alone contributed almost half. The combined carbon footprint of poppy farming and bulk morphine manufacture was modest (12%). Contrasting with prior studies of non-specific drug production, 18 36 chemicals (such as solvents, acids and alkalis) were not large contributors to morphine’s CO₂ e emissions.

To give some perspective to our findings, the carbon footprint of the manufacture of 100 mg of morphine (204 g of CO₂) is similar to that of a single use plastic anaesthetic drug tray,14 or driving an average Australian car 1 km.  

We deliberated what the wider environmental ‘carbon impact’ of a nation’s morphine production would be, but caution that such considerations would likely be inaccurate due to the lack of robust data. The total UK requirements for morphine in 2015 were estimated to be 6498 kg,24 which (if entirely intravenous) would lead to 13 250 tonnes of CO₂ e emissions. While this is an overestimation (ie, less CO₂ would be produced from oral morphine), the CO₂ e emissions of intravenous morphine production would be equivalent to an annual usage of 4400 average Australian cars.35

The UK’s Sustainable Development Unit found that ∼20% of the entire carbon footprint of the England’s National Health Service was due to drug production and use.4 There are differences in the methods of input–output LCAs7 compared with our process-based LCA. Essentially, an input–output LCA is based on the financial transactions between sectors in the economy, calculating carbon and other environmental impacts for each sector, and associating this with their final financial value (eg, kgCO₂e/£). The purchase costs for morphine for the English NHS as a proportion of the total pharmaceutical purchases for England in 2014 were £44 million of £88.9 billion37 (ie, 1/250th or 0.4%).

No companies were willing to make their data available to us for morphine in 10 mg glass phials. Belboom et al.38 studied the life cycle effects of injectable drug packaging only (not the drug itself), finding that a 1 mL glass phial filled with an unidentifiable sterile drug produced 65 g of CO₂, and “the major source of energy consumption comes from cleaning the glass vial components.” Using Belboom’s study38 as a proxy for final formulation, if 10 mg of our bulk morphine (1/10th of 24 g CO₂=2.4 g CO₂) was filled in a glass phial, the related
CO₂ e emissions would be 65 g+2.4 g=67.4 g CO₂, with the phial and final formulation contributing 96%, and the bulk morphine sulfate 4%. Such results are in the same order of magnitude to our findings, but we caution close interpretation. Even if morphine’s environmental footprint was exceptionally low compared to that of other pharmaceuticals, the final drug production stages and packaging are likely to have the largest environmental effects for most drugs. Publicly available studies of the life cycles of identifiable drugs are rare. A recent cradle-to-grave LCA of anaesthetic gases by Sherman et al. examined drugs using SciFinder39 (CAS web-based chemistry database, American Chemical Society, USA) as direct data were unavailable from the manufacturers. Drug synthesis pathways, however, change as the drug manufacturing process evolves from laboratory scale to full production, and the environmental effects can change considerably.21 Wernet et al21 studied the entire synthesis of a de-identified active pharmaceutical ingredient and found that its life cycle produced 68 g of CO₂/g drug. Wernet’s study did not include the final sterilisation processes nor packaging. Our study found that bulk morphine (ie, not including sterilisation and packaging) produced 240 g of CO₂/g morphine, considerably more than Wernet’s unidentified drug. We caution though that there may be considerable variation in processing between different drugs.

Our cradle-to-gate LCA of all processes required to produce intravenous morphine found that the CO₂/g was ~2040 g of CO₂/g morphine. Although the ‘CO₂ intensity’ of morphine is much greater (per gram) than for packaging, such packaging produces greater CO₂ e emissions due to the 100-fold greater masses involved. Our study adds weight to concerns that packaging may add greatly to the life cycle effects of many hospital products.40 We were unable to estimate the environmental effects of oral morphine tablets, though this is likely to be less than intravenous preparations due to the lesser disinfection needs,41 and reduced packaging requirements (we did not include the environmental effects of the plastic ‘giving set/drip’).

According to our study, it was challenging to identify rapid, inexpensive improvements in the environmental effects of production of morphine. Recently, GSK Victoria undertook extensive water and energy reduction programmes, saving 30 million litres of water annually through reuse, and reduced electricity consumption by 30%. Furthermore, Baxter Sydney’s factory already sourced its energy primarily from gas trigeneration, supplemented by the New South Wales electricity grid and a recently installed 500 kW solar photovoltaic system. Perhaps, we have underestimated the environmental effects of drug production since GSK and Baxter act with resource conservation in mind. Yet, even if Baxter Australia’s energy source was natural gas and the New South Wales electricity grid, this would lessen 100 mg of morphine’s related CO₂ e emissions by only ~10–15%. Yet, because of the importance of sterilisation and packaging, efforts to improve steriliser efficiencies and reducing/recycling cardboard/plastic packaging are worth exploring (eg, initiatives to recycle PVC plastic),42 particularly in the setting of carbon reduction targets.

We have shown from our study of 100 mg of morphine in plastic bags that ‘commercial in confidence’ concerns by pharmaceutical companies to LCA can be solved through collaboration leading to robust, publicly available data. Nonetheless, we were unable to obtain data regarding 10 mg of sterile morphine ampoules. As clinical end users of pharmaceuticals, it is incongruous that we are unable to obtain information regarding the environmental effects of drugs we are administering to patients, and concerted advocacy efforts by medical colleges and associations to ask for such information from pharmaceutical companies could assist further research.

The environmental footprint of a 100 mg bag of morphine was small compared to many other processes and items used in hospitals, but nevertheless important when considering worldwide pharmaceutical use. Most (90%) of morphine’s carbon footprint arose from the latter stages of production, particularly packaging and sterilisation. The environmental effects of fentanyl (another widely used opiate) for comparison with those of morphine are required to begin to provide informed, ‘environmentally aware’ drug choices. The relative environmental footprints of oral versus intravenous pharmaceuticals also warrant attention. The environmental effects of drug distribution, storage, use by clinicians (including syringes) and hospital waste disposal also require exploration. The pharmaceutical industry could reduce its carbon footprint through greater energy efficiencies and use of renewables. Improved drug packaging and augmented recycling are also needed. Clinicians and government purchasing agencies could be empowered to have LCA data to choose drugs and other products based on their environmental footprint.14

Acknowledgements The authors thank GSK and Baxter Australia for allowing access to their manufacturing site for data collection, Mark Rhodes of GSK UK for his expert advice and Simon Yoon and Bradley Keam of Baxter Australia for assistance in data collection. Tim Bowser (of SunPharma), Tom Penny (of ERM life cycle assessments) and Imogen Tennison (of the UK’s Sustainable Development Unit) gave thoughtful comments. The authors also thank Assistant Professor Craig French for manuscript review.

Contributors FMG conceived the study, obtained funding, assisted in the methods and in obtaining results, wrote and revised the manuscript, and agrees to be accountable for all aspects of the work involved. SMA assisted in study design and was the primary author who developed the methods and obtained the results. SMA also cowrote the manuscript and revisions. YO obtained the data and assisted in drafting the work as well as approving the final manuscript version. EN assisted in grant funding, data acquisition, analysis and interpretation, as well as manuscript preparation and approval of the final manuscript. KH contributed to the conception of the work, and assisted in grant funding, design of the methods and manuscript preparation. PM assisted in obtaining data and analysis, revised the manuscript and approved the final manuscript version. DS assisted in grant funding submission, data analysis and interpretation of the work, revised the manuscript and approved the final manuscript version.
Funding: Financial support for this study was provided by Australian and New Zealand College of Anaesthetists (ANZCA) grant 2014.14 and additional support for YO’s CHE14164 Integrated Industrial Project scholarship was provided by GSK Australia. A priori confidentiality agreements were signed between all authors and GSK, mandating that no precise details of any particular physical or chemical processes would be divulged in the public domain, and that GSK could not delay/prevent any manuscript submission beyond a reasonable timeframe. A similar informal agreement was also reached with Baxter, Australia, that would allow manuscript submission in a timely manner by the non-industry aligned authors. On 1 September 2015, GSK sold its opiate facilities in Australia to Sun Pharmaceutical Industries. Prior to this sale, GSK ceased production of morphine sulfate, but continues to manufacture less-refined technical morphine (95% pure by dry weight). We have kept the use of the term ‘GSK’ in this manuscript as they were the company involved in the study.

Competing interests: FMG has received research grants and honorariums from ANZCA, SMA has received research grants and honorariums from ANZCA, YO has received research grants and honorariums from GSK Australia, EN worked for GSK Australia and now for SunPharma, KH has received research grants and honorariums from GSK Australia, DS has received research grants and honorariums from ANZCA and PM works for Baxter Australia.

Provenance and peer review: Not commissioned; externally peer reviewed.

Data sharing statement: Data will not be made available due to the sensitive nature of the original source data (i.e., the preparation of morphine).
