ABSTRACT

Purpose: We initiated the Genetics of Glucose regulation in Gestation and Growth (Gen3G) prospective cohort to increase our understanding of biological, environmental and genetic determinants of glucose regulation during pregnancy and their impact on fetal development.

Participants: Between January 2010 and June 2013, we invited pregnant women aged ≥ 18 years old who visited the blood sampling in pregnancy clinic in Sherbrooke for their first trimester clinical blood samples: 1034 women accepted to participate in our cohort study.

Findings to date: At first and second trimester, we collected demographics and lifestyle questionnaires, anthropometry measures (including fat and lean mass estimated using bioimpedance), blood pressure, and blood samples. At second trimester, women completed a full 75 g oral glucose tolerance test and we collected additional blood samples. At delivery, we collected cord blood and placenta samples; obstetrical and neonatal clinical data were abstracted from electronic medical records. We also collected buffy coats and extracted DNA from maternal and/or offspring samples (placenta and blood cells) to pursue genetic and epigenetic hypotheses. So far, we have found that low adiponectin and low vitamin D maternal levels in first trimester predict higher risk of developing gestational diabetes.

Future plans: We are now in the phase of prospective follow-up of mothers and offspring 3 and 5 years postdelivery to investigate the consequences of maternal dysglycaemia during pregnancy on offspring adiposity and metabolic profile.

Trial registration number: NCT01623934.

INTRODUCTION

Obesity and diabetes are major health problems recognised worldwide.¹ Excess

Strengths and limitations of this study

- Prospective design from early pregnancy enables detailed and standardised collection of anthropometric measures and lifestyle questionnaires to give information on most known potential confounders to glycaemic regulation impairments.
- Our biobank contains both maternal and fetal blood and placenta samples.
- Participants are highly representative of the general population of pregnant women receiving obstetric care at our institution.
- As our population is mostly Caucasian, results may not be entirely generalisable to more diverse populations.

adiposity is the main risk factor for insulin resistance (IR), type 2 diabetes (T2D) and gestational diabetes mellitus (GDM), all conditions that are associated with long-term cardiometabolic complications.²⁻³ The impact of impaired glucose regulation in pregnancy is especially worrisome because of associated short-term and long-term metabolic outcomes for both mothers⁴⁻⁵ and offspring.⁶⁻⁸ Exposure to GDM during fetal development increases risk of macrosomia, fetal hyperinsulinaemia and neonatal hypoglycaemia at birth, in addition to IR, metabolic syndrome and T2D over the child's lifetime.⁶⁻⁸ This long-term phenomenon is described as fetal programming.

The Genetics of Glucose regulation in Gestation and Growth (Gen3G) cohort aimed to increase our understanding of glucose regulation determinants in pregnancy and fetal growth with emphasis on interactions between genetics and

environmental—or lifestyle—factors. We are especially interested in the roles of adipokines and vitamin D during pregnancy and in fetal development. By recruiting women at first trimester, we aimed to understand early pregnancy determinants implicated in the progressive gestational increase in IR and development of GDM. We are investigating genetic determinants of glucose regulation in pregnancy, so far based on hypothesis-driven candidate genes approaches, with the intent to use hypothesis-free approaches eventually. We are also interested in the consequences of maternal glycaemia and metabolic milieu alterations on epigenetic regulation in offspring energy and metabolic pathways.

COHORT DESCRIPTION

Gen3G is a prospective observational cohort study. We recruited pregnant women representing the general population of women in reproductive age from the Eastern Townships region, in Québec, Canada.⁹ The work conducted for the prospective follow-up during pregnancy and collection of samples and data presented here was funded by the Fonds de recherche du Québec—Santé, the Canadian Institutes of Health Research, the

Canadian Diabetes Association (CDA), and Diabète Québec. Every participant gave written informed consent before enrolment in the study, in accordance with the Declaration of Helsinki.

We recruited a total of 1034 pregnant women between January 2010 and June 2013 (see figure 1). All women were invited to participate if they received prenatal care directly at or in a health centre affiliated with the CHUS and planned delivery at the CHUS. The CHUS is the only hospital in the Eastern Township region offering obstetric care for deliveries; it provides care for about 2800 deliveries per year. Nursing staff invited women to participate during a routine prenatal visit to the CHUS Blood sampling in pregnancy clinic,⁹ all eligible women were invited with equal chance to participate in the study. If women were interested, research staff was contacted to describe the study and women could choose to contribute to different aims presented as substudies on adipokines, vitamin D and genetic determinants of gestational glucose regulation. Recruitment was eased because participation involved little additional burden to clinical requirements: drawing extra blood and answering questionnaires during visits that were clinically indicated at first and second trimesters, and collection

Figure 1 Flow chart illustrating the number of participants enrolled and active in the cohort from January 2010 to June 2013. GDM, gestational diabetes mellitus; IADPSG, International Association of the Diabetes and Pregnancy Study Groups; OGTT, oral glucose tolerance test.

of samples at delivery, all with minimal risk. If any woman was pregnant for a second time during the study timeline and wanted to participate again, the second index pregnancy was included separately and was identified with a distinct study identification number (31 women contributed 2 pregnancies during study).

Compared with the general population of pregnant women receiving prenatal care and delivering at the CHUS, Gen3G participants showed similar demographic characteristics in terms of age, parity, pre-pregnancy body mass index (BMI) and ethnic background (table 1). Similar proportions of women with abnormal glucose tolerance were detected, and GDM screening was performed at the same time during second trimester. Based on this comparison, we feel confident that the cohort is representative of the population of pregnant women in our area.

Study procedures

We collected data and samples at three time points during pregnancy (see figure 1). The first research visit (V1) was between 5 and 16 weeks of gestation, coinciding with women's first trimester prenatal clinical blood sampling as requested by their primary care physician. During this visit, we collected demographic data, medical history and anthropometric measurements; women completed questionnaires about lifestyle, and we collected extra blood samples during the clinically indicated blood draw (the majority during a 50 g

glucose challenge test (GCT)). Most women performed this test as our cohort study happened in conjunction with a CDA-funded study (principal investigator: J-LA) investigating the value of a first trimester 50 g GCT in identifying women at risk of GDM later during pregnancy. Women were excluded (n=9) if they: had known pre-pregnancy diabetes, took medication that influenced glucose tolerance, had glycated haemoglobin (HbA1c) $\geq 6.5\%$ or 1 h glucose ≥ 10.3 mmol/L post-50 g GCT, as this was classified as overt diabetes based on 2008 CDA criteria.¹⁰ Maternal glycaemia was kept blinded if results of glucose levels after the 50 g GCT were <10.3 mmol/L (per protocol of CDA-funded study).

The second visit (V2) was planned between 24 and 30 weeks, concomitantly with clinically indicated GDM screening test—in line with universal second trimester screening recommendations (both CDA and International Association of the Diabetes and Pregnancy Study Groups (IADPSG) guidelines).^{10 11} During V2, we updated medical history, repeated anthropometry measures, and women completed the same questionnaires about lifestyle. We collected extra blood samples at each point of the 75 g oral glucose tolerance test (OGTT; fasting, 1 and 2 h). Women diagnosed with GDM at that visit were followed up and treated according to 2008 CDA guidelines adopted at that time at our institution. Between V1 and V2, we excluded 81 (7.8%) women per protocol for miscarriage, medical abortions or health problems that prohibited

Table 1 Demographic characteristics of Gen3G participants and of the general population of pregnant women who delivered at the CHUS over same time period

Characteristics	Gen3G participants (n=1024*)		CHUS patients, between 2008 and 2011 (n=7710)	
	N	Median [IQR] or N (%)	N	Median [IQR] or N (%)
Age (years)	1024	28.0 [25.0–31.0]	7507	28.0 [24.0–31.0]
European descent	1012	964 (95.3)	5224	4758 (91.1)
Primiparity	1024	354 (34.6)	8579†	2849 (33.2)
Self-reported pre-pregnancy BMI (kg/m ²)	1014	23.2 [20.9–27.3]	7225	23.2 [20.9–26.7]
Abnormal glucose tolerance at first trimester‡	1024	9 (0.9)	3047	56 (1.8)
GDM diagnosis at V2			5354	530 (9.9)§
According to CDA¶	823	43 (5.2)		
According to IADPSG	823	80 (8.9)		
Gestational week at which GDM screening was performed in the second trimester	893	26.2 [25.6–27.1]	5361	26.4 [26.0–28.0]

2008 CDA criteria: 50 g glucose challenge followed by a 1 h plasma glucose. If 1 h plasma glucose <7.8 , no GDM. If 1 h plasma glucose ≥ 10.3 , GDM diagnosis. If 1 h plasma glucose is 7.8–10.2, reassess with a 75 g OGTT (fasting plasma glucose <5.3 , 1 h plasma glucose <10.6 , 2 h plasma glucose <8.9 ; if one value is exceeded, IGT diagnosis; if more than one value is exceeded, GDM diagnosis). IADPSG criteria: 75 g OGTT with fasting, 1 and 2 h plasma glucose. If fasting plasma glucose ≥ 5.1 and/or 1 h plasma glucose ≥ 10.0 and/or 2 h plasma glucose ≥ 8.5 , GDM is diagnosed.

*In total, 1034 participants accepted inclusion in the study, but multiple pregnancies (n=10) were excluded from these analyses.

†Total number of pregnancies, completed or not, seen at least once at the CHUS between 2008 and 2011.

‡Abnormal glucose tolerance was defined as reaching a blood glucose level ≥ 10.3 mmol/L 1 h after the 50 g GCT.

§Determined by the per cent of women referred to our institution's Endocrinology in Pregnancy Clinic; not all women performed 75 g OGTT or performed it at our institution.

¶Including GDM and IGT diagnoses as per the 2008 CDA guidelines for glucose levels above threshold at one time point (IGT diagnosis) or two time points (GDM diagnosis) during the 75 g OGTT (three points: fasting, 1 and 2 h).

BMI, body mass index; CDA, Canadian Diabetes Association; CHUS, Centre Hospitalier Universitaire de Sherbrooke; GDM, gestational diabetes mellitus; Gen3G, Genetics of Glucose regulation in Gestation and Growth; IADPSG, International Association of the Diabetes and Pregnancy Study Groups; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

participation (see figure 1). Another 45 (4.4%) participants moved away or declined further participation before V2.

At the end of pregnancy, we successfully collected clinical data from electronic hospital records for the majority of participants (82.9% of women recruited; 95.1% of women still active at V2). Information concerning 15 deliveries (1.7% of women still part of the study after V2) is missing or was excluded due to: delivery at another institution, active withdrawal or stillbirth. We collaborated with research in obstetric services (led by collaborator Dr J-C Pasquier) which offered trained research staff on call 24 h per day, 7 days per week and were directly contacted by clinical nurses from the obstetric department each time a study participant was admitted for delivery. These services were in place for multiple clinical research studies apart from Gen3G. Based on this unique set-up and in collaboration with researchers from the obstetric department, collection of biological samples for 736 (84.1%) deliveries was possible. Sample collection was missed for 147 deliveries (15.9%) for the following reasons: short time between participant admission and delivery, clinical staff omitted to contact research staff, communication issues (pager failure), coagulated cord blood before arrival of research staff, break in research staff services (holidays).

Table 2 shows characteristics of women recruited in Gen3G that were followed until delivery compared with women who were excluded, withdrawn or lost to follow-up. No significant demographic differences between groups were observed. Familial history of diabetes was slightly more common in women who remained in the study. The proportion of women with positive personal history of previous GDM or macrosomic offspring was not different between women who completed the study and those who did not.

Data collection

Maternal anthropometry and vital signs (V1, V2)

Anthropometry was measured according to standardised procedures: weight (in kg) was measured with a

calibrated electronic scale with bare feet in light clothing; height (in m) was measured with a wall stadiometer without shoes. BMI was calculated as weight divided by squared height (kg/m^2). Body fat percentage (BFP) was estimated based on lean body mass measured by bioimpedance using a standing foot-to-foot scale (TBF-300A; Tanita. Coefficient of variation (CV): 2.1%¹²). Waist circumference (WC) was measured with a flexible measuring tape (in cm) above the top of the iliac crest; measurement was performed twice¹³ and the average was recorded. Systolic and diastolic blood pressures were measured (in mm Hg) thrice in the sitting position after 5 min of rest; the average of these three measurements is used in analyses (see table 3 for a general overview of characteristics in participants and offspring).

Neonatal anthropometry (delivery)

Weight (in g) and length (in cm) of newborns were measured following standard clinical procedures, with an electronic scale and a measuring tape by obstetrics nurses within 2 h of delivery. We collected these and other relevant clinical information available in electronic medical records (detailed in box 1). In January 2012, neonate skinfolds thickness (SFT) measurements were added to the protocol. We measured triceps, biceps, subscapular and suprailiac skinfolds (in mm) in duplicate on the right side of neonates. Trained research staff measured SFT following a standard procedure¹⁴ with a calibrated skinfold caliper (AMG Medical). Triceps SFT was taken parallel to the long axis, midway between the acromial and the olecranon with the arm slightly flexed. Biceps SFT was measured at the middle point on the front of the slightly extended arm. Subscapular SFT was taken 1–2 cm below the lower tip of the scapula and suprailiac SFT was taken on the natural fold of the skin just above the iliac crest. Measures were recorded when the most constant reading was read on the caliper (considering neonate's movements). Triplicate measurement was taken if duplicate varied over 10.0%. We successfully measured SFT in a total of 265 newborns (31.0% of total

Table 2 Demographic characteristics of women recruited in Gen3G that were followed until delivery compared with women who were excluded, withdrawn or lost to follow-up

Characteristics	Participants with delivery research data collected (n=854)	Participants lost to follow-up before or at delivery (n=170*)	p Value
N (%) or median [IQR]			
Age (years)	28.0 [25.0–31.0]	28.0 [25.0–31.0]	0.46
Primiparity	294 (34.4)	60 (35.3)	0.45
Self-reported pre-pregnancy BMI (kg/m^2)	23.3 [20.9–27.3]	22.7 [20.9–27.5]	0.49
European descent	814 (95.3)	163 (90.6)	0.11

Delivery: obstetric data abstracted from medical records (n=862)

Gestational age at delivery
 Diagnostics at delivery (GDM: type of treatment; other pregnancy complications)
 Labor details (spontaneous or induction, length of labour, analgesia, steroids, antibiotics, anaesthesia)
 Delivery date and time, type (natural, caesarean)
 Episiotomy, laceration (perineal, vaginal), approximate blood loss, amniotic fluid description, umbilical cord description

Delivery: neonate data abstracted from medical records (n=854)

Sex of neonate
 Alive/dead status, resuscitation (type of air feed), transfer to neonatal intensive care unit
 APGAR scores (1 and 5 min)
 First and second or third trimesters echography details (when performed)
 Neonatal clinical evaluation recorded in electronic medical records: malformations, head symmetry, skin colouration, consciousness level
 Total birth length, head circumference
 Feeding during hospitalisation and intent (maternal breast feeding/formula)
 Length of stay for hospitalisation following delivery (excluding subsequent visits after discharge)
 Neonatal complications (during hospitalisation postdelivery): neonatology unit care, bradycardia, respiratory problems, hypoglycaemia, hypocalcaemia, hyperbilirubinaemia, polycythaemia, fractures/dislocations, intensive care stay, respiratory therapy, others
 Placental weight

measure SFT. Two trained research staff repeated SFT measures on the same 40 newborns (15.0%); interindividual variability was 1.5%.

Medical history (V1, V2, delivery)

Trained research staff administered standardised questionnaires during study visits to determine participants'

medical history. Clinical data regarding any late pregnancy medical updates, perinatal events, delivery details and neonate health parameters at birth were abstracted from electronic health records. Full list of data collected is detailed in [box 1](#).

Lifestyle questionnaires (V1, V2)

Trained research staff administered standardised questionnaires¹⁵ at both visits to collect details on diet (food type and frequency), sun exposure, and physical and sedentary activities. Full list of data collected is detailed in [box 1](#).

Maternal blood samples (V1, V2)

At V1, extra blood was collected to obtain plasma and buffy coat 1 h after the 50 g GCT, for storage (for planned DNA extraction). At V2, we collected extra blood samples at fasting, 1 and 2 h over the course of the 75 g OGTT to store plasma and buffy coat, at the same time of clinically indicated blood draws for GDM diagnosis (see [table 4](#)).

Placenta and cord blood samples

At delivery, we collected cord blood for serum, plasma, buffy coat, whole blood and RNA (in PAXgene tubes). One cm³ of maternal and fetal placenta tissue was collected approximately 5 cm from the cord immediately after observation by the obstetrician. These samples were preserved in RNA Later (Qiagen) as indicated by the manufacturer and kept at −80°C for later RNA extraction (see [table 4](#)).

Handling of biological specimen

To inhibit protein degradation, aprotinin (1 µL/mL of blood) was added to each blood sample (V1, V2, cord blood) before centrifugation at 2500g for 10 min at 4°C. Plasma, serum, whole blood and buffy coats were aliquoted (300–500 µL/aliquot), wrapped in paraffin paper to avoid evaporation, and stored at −80°C. All participants consented to additional analyses, related to our original research questions, using their own and their offspring samples; most also consented to donate any remaining samples to our anonymised biobank (n=996). Maximum numbers of samples collected per type of sample are listed in [table 4](#).

Biomarkers measurement

The CHUS biomedical laboratory performed the following biochemical measurements on fresh samples (time points listed in [table 5](#)): plasma glucose (by the glucose hexokinase method; Roche Diagnostics), fasting total cholesterol, high-density lipoprotein-cholesterol and triglycerides (by colorimetric methods; Johnson & Johnson Clinical Diagnostics), low-density lipoprotein-cholesterol levels (calculated using Friedewald's equation), HbA1c (by HPLC; Bio-Rad VARIANT), calcium (by colorimetric assay), parathormone (by electrochemiluminescent assay) and phosphorus (by photometry) as previously described.¹⁷ Vitamin D (25OHD₂ and 25OHD₃) levels were measured in a biochemistry research laboratory (led by collaborator Dr G Fink) at our institution by liquid–liquid extraction followed by liquid chromatography/electrospray tandem mass spectrometry (Quattro micro mass spectrometer; Waters).¹⁸ The sum of

Table 4 Biological samples of Gen3G mothers and offspring

Time point	Sample type (additive)	Maximum number of aliquots	Number of participants that accepted biobanking
V1	Plasma (EDTA)	8	996
First trimester after 50 g GCT or non-fasting (2010–2013)	Buffy coat (EDTA)	1	962
V2	Plasma T0—fasting (EDTA)	8	843
Second trimester during 75 g OGTT (2010–2013)	Plasma T1 h (EDTA)	8	
	Plasma at T2 h (EDTA)	8	
	Buffy coat T0 (EDTA)	1	821
	Buffy coat T2 h (EDTA)	1	
Delivery (2010–2014)	Plasma (EDTA)	16	662
	Serum (SST)	4	552
	Whole cord blood (NaF, EDTA)	4	403
	Buffy coat (EDTA)	3	640
	RNA PAXgene*	—	597
	Placenta, fetal side (RNA Later)	—	694
	Placenta, maternal side (RNA Later)	—	

Additives: RNA Later, ammonium sulfate; SST, coagulation activator and serum separator; NaF, fluoride sodium.

Data were compiled and accurate on 12 May 2014.

Biobank: denominised data and samples accessible for projects related to other pregnancy-related conditions.

*RNA PAXgene additive induces cell lysis, stabilises RNA and reduces RNA degradation and gene transcription. This tube was not aliquoted.

GCT, glucose challenge test; Gen3G, Genetics of Glucose regulation in Gestation and Growth; OGTT, oral glucose tolerance test; T0, samples taken under fast; T1 h, samples taken 1 h after the start of the 75 g OGTT; T2 h, samples taken 2 h after the start of the 75 g OGTT.

*Pregestational weight was self-reported. Other starred variables were extracted from electronic hospital records.

Apo A, apolipoprotein A; Apo B, apolipoprotein B; Gen3G, Genetics of Glucose regulation in Gestation and Growth; HbA1c, glycated haemoglobin; HCO₃, bicarbonate concentration; HDL, high-density lipoprotein; LDL, low-density lipoprotein; OGTT, oral glucose tolerance test; pCO₂, partial pressure of carbon dioxide; pH, acidity; pO₂, partial pressure of oxygen; TNF, tumour necrosis factor.

25OHD₂ and 25OHD₃ levels was considered total plasma 25OHD levels. Minimum detectable concentration (MDC) was 1.25 nmol/L for 25OHD₂ and 6.25 nmol/L for 25OHD₃. Intra-assay and interassay CVs were, respectively, 7.4% and 4.1% for 25OHD₂ and 4.7% and 2.9% for 25OHD₃.

We performed the following biomarker measurements in our common endocrinology research laboratory (see table 5 for timing and number of samples analysed to date):

- ▶ Cord blood glucose was measured by the glucose hexokinase method (Roche Diagnostics). MDC was 2.5 mM. Intra-assay and interassay CVs were 0.19% and 1.84%.
- ▶ Total adiponectin levels were measured by radioimmunoassay (EMD Millipore). MDC was 0.78 ng/mL. Intra-assay and inter-assay CVs were both <10%.
- ▶ Insulin, leptin, C peptide and tumour necrosis factor (TNF) α concentrations were measured using a multiplexed particle-based flow cytometric assay (Human

Milliplex map kits, EMD Millipore). MDC and lowest curve standard were, respectively, 87 and 45.7 pg/mL for insulin, 41 and 45.7 pg/mL for leptin, 9.5 and 22.9 pg/mL for C peptide, and 0.30 and 0.90 pg/mL for TNF α . Intra-assay and inter-assay CVs were, respectively, <10% and <15% for all analytes.

Plasma glucose and insulin values, either under fast or during the 75 g OGTT, were used to calculate the homeostasis model of assessment of IR (HOMA-IR) as well as dynamic indices of insulin sensitivity and secretion: the Matsuda index (validated in pregnancy¹⁹), the total area under the curve of insulin divided by the total area under the curve of glucose (AUC_{insulin/glucose}), and insulin secretion-sensitivity index (ISSI)-2 according to published methods.^{11 19–21}

POWER CALCULATION

Gen3G was planned to recruit over 1000 pregnant women to have adequate power to investigate

biomarkers associated with risk of developing GDM and related to impaired glucose regulation in pregnancy. For example, we calculated that we would have 85% power to detect an OR=1.32 increased risk of GDM for each 1 µg/mL reduction of adiponectin (two-sided α 0.05). For genetic analyses, we based our power calculation on candidate genes that were previously shown to influence glycaemic traits in non-pregnant populations: depending on the region and number of single nucleotide polymorphisms tested, we estimated that we would have 80% power to explain between 1.0% and 1.8% of variance of glycaemic-related traits (using continuous measures). We were well aware that we did not have the sample size to conduct genome-wide analyses, but that our sample size and richness of phenotypes would allow us to contribute data to meta-analyses involving multiple cohorts.

FINDINGS TO DATE

Gen3G completed its recruitment in June 2013 and its follow-up until last delivery in February 2014. Accordingly, major published findings at the time of publication of this manuscript are summarised below.

Evaluating adiponectin and the risk of developing GDM

We investigated the role of adiponectin in glucose regulation during pregnancy and the risk of developing GDM²² as defined by IADPSG criteria. We demonstrated that women who developed GDM had lower first trimester adiponectin levels (9.67 ± 3.84 vs 11.92 ± 4.59 µg/mL; $p=0.004$) when compared with women who remained normoglycaemic. Lower adiponectin levels were associated with a higher risk of developing GDM (OR=1.14 (95% CI 1.04 to 1.25) per 1 µg/mL decrease in adiponectin levels; crude $p=0.004$) independent of adiposity (BMI, BFP or WC) and glycaemic regulation (HbA1c or glycaemia post-50 g GCT) at first trimester (OR=1.12 (95% CI 1.02 to 1.23); $p=0.02$ in fully adjusted models). Lower adiponectin levels at first and second trimesters were also associated with higher second trimester IR represented by HOMA-IR (both: $r=-0.22$, $p<0.0001$) and Matsuda index (respectively, $r=0.28$ and $r=0.29$, $p<0.0001$ for both), independent of age and BMI.

Understanding the role of TNF α in glucose regulation and IR in pregnancy

The role of TNF α in pregnancy-related IR has been examined^{20–23–25} but studies reported conflicting findings. We investigated the association between TNF α levels at first and second trimesters and IR in 756 women from Gen3G, taking into account confounding factors such as adiposity and other IR biomarkers. Our results show that higher maternal circulating TNF α levels were associated with higher IR as assessed by various indices (HOMA-IR: $r=0.37$, Matsuda: $r=-0.30$; $p<0.0001$ for both), independently from age, BMI, triglycerides and adiponectin levels.²⁶ Interestingly, we detailed for the first time the dynamic response of

circulating TNF α over the course of a 75 g OGTT in pregnant women. This study shows that at second trimester, TNF α levels dynamics varied differently in women categorised with elevated IR compared with women categorised with the lowest IR.

Assessing circulating vitamin D as a predictor of GDM

Among other biomarkers of interest, we investigated maternal vitamin D circulating levels at first trimester in relation with glycaemic regulation at second trimester and the risk of developing GDM. We demonstrated that lower first trimester 25OHD levels were associated with higher risk of developing GDM (OR=1.48 per SD decrease in 25OHD levels; $p=0.04$) within model adjusted for vitamin D-related confounding factors (such as season of sampling, parathormone levels and a vitamin D lifestyle score that included dietary intake and sunlight exposure) and known GDM risk factors (history of GDM or macrosomic newborn, maternal age, familial history of diabetes, ethnic background, parity and WC).²⁷ Lower first trimester 25OHD levels were also associated with a higher index of IR (HOMA-IR; $r=-0.08$; $p=0.03$), a lower Matsuda index ($r=0.13$; $p=0.001$) and a lower ISSI-2 ($r=0.08$; $p=0.04$) assessed at second trimester.

STRENGTHS AND LIMITATIONS

One of the Gen3G cohort's main strength is its prospective design from early pregnancy to delivery. The large sample size and population-based design allow inferring results to the general population of pregnant women in our region, but also to other populations who are mainly of European descent. We conducted detailed and standardised anthropometric measurements and lifestyle questionnaires that allow us to take into account most known potential confounders to glycaemic regulation impairments. We collected maternal blood samples at multiple time points of pregnancy and we successfully obtained cord blood and/or placenta in about 80% of deliveries. Placenta material in particular is a feature that few mother-child cohorts have. This opens the possibility of investigating epigenetics and gene expression (RNA and/or protein) specific to the role of placenta in health and diseases related to pregnancy. Gen3G sample size and collection of DNA on both mother and offspring also allow sufficient power to perform genetic association studies, for candidate genes approaches if considering Gen3G sample size alone, or as a decent additional cohort to contribute to meta-analyses. Integration of both genetics and epigenetics in our study is particularly attractive for questions related to the developmental origin of health and disease field. Of note, follow-up of mothers and children at 3 and 5 years old is ongoing. Visits include questionnaires, measures of anthropometry and collection of biological samples for genetic analyses and measures of biomarkers related to adiposity and glycaemia in both mothers and children. One other major strength resides in the vision the investigators invested in

this cohort. Biological samples were collected, aliquoted and stored for future research questions and hypotheses related either to glycaemic regulation or other disorders of pregnancy (biobank, maximum $n=996$).

Limitations include the absence of fasting blood samples at first trimester, which would have allowed calculation of the IR index HOMA-IR early in pregnancy. Moreover, some biomarkers measured at first trimester are more sensitive to fasting status (eg, leptin and TNF α); not being able to measure their fasted levels at first trimester might have influenced our interpretation of change over the course of pregnancy. Fasting samples would also have been particularly useful for measurement of potential biomarkers that are highly sensitive to food intake, such as lipid, carbohydrates and amino acids metabolites that are now part of the upcoming field of metabolomics; however, emerging literature suggests that postglucose load metabolomics might be highly informative for investigations of weight and glycaemic-related traits.^{28–30} In addition, as the Eastern Townships population is mostly of European descent, our homogenous cohort population prevents generalisation of our results to populations with other ethnic background (Asian, Hispanic, Indigenous, African), who usually have a higher risk of GDM compared with women of European descent.

In hindsight, our data would have been enriched by adding a research visit during third trimester, for which we relied on medical records to collect end-of-pregnancy data that are not as reliable as standardised research assessments. Similarly, collection of paternal data and samples would have increased our ability to take into account familial factors and investigate parent-of-origin effect in our genetic studies. Also, emerging interests in microbiota and its relation to metabolism in pregnancy and offspring also lead us to believe that collecting stool, urine and amniotic fluid samples would have been of great value in our cohort. However, our choices of balancing ease of recruitment, participants' burden and additional procedures, were to limit attrition—which was consequently relatively small compared with similar studies.^{31 32}

Future plans

We are now in the phase of prospective follow-up of mothers and offspring 3 and 5 years postdelivery to investigate the consequences of maternal dysglycaemia during pregnancy on offspring adiposity and metabolic profile. We are seeking funding to enrich phenotypic characterisation and additional samples collection for epigenetic and biomarkers studies. We hope to continue to follow-up Gen3G participants over many years to come, if we have adequate funding and support.

COLLABORATION

Collaboration propositions are welcome, either in the form of accessing questionnaire-based data and/or

biological samples. Investigators interested in GDM or other disorders of pregnancy can propose their ideas to have access to data/samples stored in our biobank. To discuss collaboration possibilities, investigators are invited to contact M-FH and PP (mhivert@partners.org; patrice.perron@usherbrooke.ca).
