Cohort profile: prevalence of valvular heart disease in community patients with suspected heart failure in UK

Anna Marciniak,1 Keli Glover,2 Rajan Sharma1,2

ABSTRACT

Purpose: The aim of this study was to evaluate the proportion of suspected heart failure patients with significant valvular heart disease. Early diagnosis of valve disease is essential as delay can limit treatment and negatively affect prognosis for undiagnosed patients. The prevalence of unsuspected valve disease in the community is uncertain.

Participants: We prospectively evaluated 79 043 patients, between 2001 and 2011, who were referred to a community open access echocardiography service for suspected heart failure. All patients underwent a standard transthoracic echocardiogram according to British Society of Echocardiography guidelines.

Findings to date: Of the total number, 29 682 patients (37.5%) were diagnosed with mild valve disease, 8983 patients (11.3%) had moderate valve disease and 2134 patients (2.7%) had severe valve disease. Of the total number of patients scanned, the prevalence of aortic stenosis, aortic regurgitation, mitral stenosis, mitral regurgitation was 10%, 8.4%, 1%, and 12.5% respectively. 18% had tricuspid regurgitation. 5% had disease involving one or more valves.

Conclusions: Of patients with suspected heart failure in the primary care setting, a significant proportion have important valvular heart disease. These patients are at high risk of future cardiac events and will require onward referral for further evaluation. We recommend that readily available community echocardiography services should be provided for general practitioners as this will result in early detection of valve disease.

INTRODUCTION

Valvular heart disease is an important cause of morbidity and mortality. Early detection and treatment is advocated to improve long-term outcome.1, 2 However, a significant proportion of patients with valve disease present late, when the long-term benefits of intervention are less certain. The Euro Heart Survey and other observational studies have demonstrated that around 50% patients having surgery for valve disease were in New York Heart Association III or IV which unnecessarily increases postoperative complications and further mortality.3-6

Strengths and limitations of this study

- This is the first largest community study, involving 79 043 patients, looking at the prevalence of valvular heart disease in patients with suspected heart failure, referred by general practitioners.
- The study demonstrated that the large proportion of these patients had a significant valvular heart disease that puts them into a high risk of future cardiac events.
- The study showed the importance of the open access echo service for general practitioners where immediate diagnosis of heart failure or valve disease could be confirmed.
- There is lack of demographic data; however, this is the first study which presents the prevalence of valvular heart disease in such a large number of patients in community.
- There is no data on the prevalence of coronary artery disease in this group of patients.

The study of Nkomo et al identified unsuspected valve disease occurring in 1.8% of healthy adults referred for echocardiography. In contrast, the prevalence of moderate or severe valve disease was 2.5% in healthy adults not being referred for echocardiography.7 The differences in prevalence suggest that there is still a significant number of patients with under diagnosed valve disease.

Among patients admitted to hospital with heart failure the prevalence of valve disease is high (21% as demonstrated by the study of Philbin et al8). However, the prevalence of significant valve disease in patients with suspected heart failure in the community is unclear. The aim of this study was to evaluate the prevalence of significant valve disease in a large group of patients with suspected heart failure in the community setting.

METHODS

Study population

Between January 2001 and 2011 we prospectively acquired the data on patients who were referred to a community open access echocardiography service for suspected heart
failure. These data were then retrospectively reviewed. Patients were referred for an echocardiogram by their general practitioner (GP) with heart failure suspected based on clinical symptoms and signs and/or elevated brain natriuretic peptide. The referral base included 25 different regions in the UK.

Echocardiography
All patients underwent a standard transthoracic echocardiogram according to British Society of Echocardiography guidelines from 2005. The assessment of valve regurgitation was performed based on the quantitative parameters including regurgitant volume and effective regurgitant orifice area and supported by semiquantitative methods like vena contracta width and pressure half time.

The severity of valve stenosis was assessed based on the peak gradient and velocity, mean gradient and velocity and valve area. The severity of valve pathology was graded as mild, moderate or severe degree according to British Society of Echocardiography guidelines.

All studies performed and reported by experienced sonographers who were accredited in performing transthoracic examination by British Society of Echocardiography. Twenty per cent of these scans were independently reviewed by a second accredited experienced sonographer or the clinical lead.

RESULTS

Patient characteristics
A total of 79,043 patients aged >18 years underwent transthoracic echocardiography performed by open access echo service (InHealth Echotech Echocardiography) following a referral from GP with suspected diagnosis of heart failure based on clinical signs and symptoms and/or elevated brain natriuretic peptide.

Echocardiographic results
Of 79,043 patients, 14.1% (11,117 patients) were diagnosed with moderate and severe degree of valve disease with predominantly left-sided valve disease 8.71% (6870 patients). The most common left-sided valve pathology was mitral regurgitation which affected 12.5% (9882 patients) of studied group, the second commonest valve pathology was aortic stenosis 10.05% (7964 patients), followed by aortic regurgitation 8.44% (6673 patients) and the least common being mitral stenosis 1.09% (860 patients). The detailed results of the degree of valve disease are presented in table 1.

As expected 37.5% (29,694 patients) of patients were diagnosed with mild valve pathology, followed by moderate valve pathology in 11.3% (8932 patients) and severe degree in 2.7% (2203 patients), figure 1.

The interobserver variability in grading the severity of valve disease was 3% with intraobserver variability of 2%. This data was obtained from a snapshot of 200 patients.

DISCUSSION
This is the largest community study (79,043 patients) which has investigated the prevalence of valve disease in...
patients referred by GPs with a potential diagnosis of heart failure. Of 79,041 patient evaluated, 37.5% had mild valve disease, 11.3% moderate valve disease and 2.7% severe valve disease. This contrasts with the proportion of patients with mild, moderate and severely impaired LV systolic function being 3%, 4% and 5%, respectively. The results have important clinical implications as these patients are at high risk of future cardiac events and a large proportion should be considered for specialist evaluation.

Unsuspected significant valvular heart disease affects at least 2.5% of a healthy US population. The prevalence increases with age, such that 13% of people older than 75 years have at least moderate aortic or mitral valve disease. Berry et al demonstrated that heart failure complicated 25% of admissions of patients with valve disease therefore early detection is important. Our study has investigated an intermediate set of patients who have not been hospitalised but have been seen in primary care with an echocardiogram request then made after evaluation to look for heart failure.

The implications of this study are large. Increasingly it is recognised that physical signs alone in particular auscultation has a limited sensitivity being insufficient for the diagnosis of valve disease. At least a third of patients with severe aortic stenosis are not referred for surgery even when clinically indicated at presentation. Echocardiography is the gold standard for diagnosis of valve disease, the assessment of the valve disease severity and guiding intervention. Given the potential burden of valve disease in the community as demonstrated by our study, much greater provision of echocardiography is required to aid GPs in the diagnosis and management of valve disease.

It has been previously suggested by Arden et al that there needs to be local, national and international educational programmes to encourage GPs and hospital-based non-cardiologists to refer patients with possible valve disease to specialist valve clinics. There is no data available on the outcome of these patients referred through open access echo service yet.

We recommend that readily available community echocardiography services should be provided for GPs as this will result in a lower threshold for referral and early detection of valve disease.
