Did case-based payment influence surgical readmission rates in France? A retrospective study

ABSTRACT

Objectives To determine whether implementation of a case-based payment system changed all-cause readmission rates in the 30 days following discharge after surgery, we analysed all surgical procedures performed in all hospitals in France before (2002–2004), during (2005–2008) and after (2009–2012) its implementation.

Setting Our study is based on claims data for all surgical procedures performed in all acute care hospitals with >300 surgical admissions per year (740 hospitals) in France over 11 years (2002–2012; n=51.6 million admissions).

Interventions We analysed all-cause 30-day readmission rates after surgery using a logistic regression model and an interrupted time series analysis.

Results The overall 30-day all-cause readmission rate following discharge after surgery increased from 8.8% to 10.0% (P<0.001) for the public sector and from 5.9% to 8.6% (P<0.001) for the private sector. Interrupted time series models revealed a significant linear increase in readmission rates over the study period in all types of hospitals. However, the implementation of case-based payment was only associated with a significant increase in rehospitalisation rates for private hospitals (P<0.001).

Conclusion In France, the increase in the readmission rate appears to be relatively steady in both the private and public sector but appears not to have been affected by the introduction of a case-based payment system after accounting for changes in care practices in the public sector.

INTRODUCTION

Financing hospitals is a challenge for any healthcare system. Many countries in the Organisation for Economic Cooperation and Development have chosen payment by diagnosis-related group (DRG). In 1983, the USA was the first country to introduce a case-based payment system according to DRGs of patients insured by Medicare.1–5 Many countries around the world6 chose to adopt this model as a tool to regulate hospital expenditure. The USA applied DRG-based reimbursement to one specific patient group, those 65 years and over (Medicare) and eventually for the poor (Medicaid). In other countries, only a part of hospital reimbursement is based on the DRG system, as in Portugal,5 6 where this payment system concerns only certain care activities. To our knowledge, only France and Norway have implemented this case-based payment system to finance all hospital care activities since the early 2000s.7 8

Other countries, like Belgium, are considering the implementation of a similar case-based payment system,9 but wonder whether it would induce certain unintended effects such as encouraging hospitals to increase their activity to improve their financial balance sheets. Moreover, whether or not there was improvement in quality of care10–12 with regard to the decreased length of stays and in terms of mortality and readmission rates is a matter of debate13–15. Although hospital readmissions, when considered alone, can be used as an indirect marker of healthcare quality, their value in this setting is controversial.16 17 In addition, there is some evidence that the implementation of a tariff system based on activity would lead to an increase in
rehospitalisation so as to maximise hospital revenues.\textsuperscript{18–21} This effect was so feared in the USA and England that policy-makers imposed penalties for hospitals with abnormally high rehospitalisation rates.\textsuperscript{22–24}

The medical information system in France has gathered exhaustive data on hospital activity since 1997, well before the implementation of case-based reimbursement in 2005. It is thus possible to obtain baseline rehospitalisation rates before the implementation of the case-based payment system. Since case-based payment was applied to all hospital activities, it is relatively easy to measure the evolution of readmissions after surgical procedures over the period of implementation.

The aim of this study is to determine whether implementation of case-based payment system was associated with a change in all-cause rehospitalisation rates in France. To do this, we compared rehospitalisations before the implementation of the case-based payment system (2002–2004), which was introduced stepwise in the middle of the study period (2005–2008) and after the implementation (2009–2012), after adjustment for the principal characteristics of patients. Previous studies conducted in France have not analysed the evolution of readmission rates over time\textsuperscript{25} or only examined certain regions,\textsuperscript{13} or were based only on specific diseases.\textsuperscript{26,27} In this study, we include all surgical procedures and consider all readmissions, whatever the surgical subspecialty and cause of readmission.\medskip

\section*{METHODS}

\subsection*{Source of data}

The hospital discharge abstract database (Programme de Médicalisation des Systèmes d’Informations (PMSI)) contains individual, exhaustive and linkable but anonymous data on healthcare use for the whole French population and collects primary and associated diagnoses (secondary events and comorbidities) encoded using WHO International Statistical Classification of Diseases and Related Health Problems, 10th revision, and procedures performed during all hospital stays using the common classification system for medical procedures (Classification commune des actes médicaux). The very good quality of the French hospital database has previously been evaluated and has enabled us to carry out several epidemiological and health services research studies concerning hospitalised patients in France.\textsuperscript{25,26,28–35} The study was approved by the National Committee for Data Protection.

\subsection*{Population}

This study was a retrospective multicentre study based on nationwide PMSI data.

We include all patients admitted to all acute care hospitals with surgical wards (740 hospitals including 295 public hospitals and 445 private hospitals) for surgical procedures (as defined by the French DRG classification) over 11 years (2002–2012). Hospitals with fewer than 300 surgical admissions per year were not included, because many of them closed during the study period. We considered separately public and private hospitals, as hospital funding was completely different between these two types before the introduction of case-based payment in all hospitals. The 46 private not-for-profit hospitals were classified in the public sector, as their hospital funding was the same as for public hospitals.

\subsection*{Main outcome measure: readmission within 30 days following discharge}

For each selected surgery admission, the time from patient discharge to a new admission was calculated according to the linked information. Initial hospitalisations and stays ending in death or transfer, iterative treatments and neonatology were excluded. In ‘iterative treatments’, we considered 1 day admissions for treatments such as chemotherapy, radiation therapy and haemodialysis. All-cause readmission was defined as ‘a new hospitalisation within 30 days\textsuperscript{30} following discharge after an admission for surgery, whatever the reason for this second admission’ as done before,\textsuperscript{25,26} that is, if a patient was readmitted for a reason other than the diagnosis for the first admission, it was still considered a readmission. The hospital where the readmission took place was also noted.

\subsection*{Variables studied: characteristics related to readmission}

The characteristics of the admissions were studied according to the variables available in the national medical-administrative database, namely year of hospitalisation, age, gender, mode of admission (from home, via an emergency service and transfer), the type of hospital, morbidity (Charlson score, Major Diagnostic Categories of French classification in DRGs that we called DRG groups) and length of stay.\textsuperscript{15} We also added the urban/rural classification of patients’ place of residence according to the French institute of statistics and censuses. We subdivided information regarding urban areas into three categories: city centres, suburbs of big cities and small towns.

\subsection*{Statistical analysis}

In the first analysis, we studied the influence of the variables defined above (all dichotomised) on readmission at 30 days with two logistic regression models. The probability of readmission was analysed separately for the two types of hospital sector (ie, public and private). The first model (M0) concerned all hospital admissions for surgery.

The second model (M1) excluded DRG groups with low volumes of activity (burns, infectious diseases, HIV diseases, multiple trauma, psychiatry in acute care and other types of care). They also excluded cases with major modifications in care practices during the period, either for changes in care management (eg, in ophthalmology) or therapeutic changes for the treatment of HIV. Regarding ophthalmological surgery, since cataract surgery is more and more frequently performed to one eye and rapidly after to the other (<1 month after), we had to take into account this change with time, which
results in an increase in readmission rates in ophthalmology substantially greater than in other specialties.

In the second analysis, an interrupted time series analysis was performed to measure changes in the readmission rate over time while taking into account the variables defined above. This model used monthly readmission rates over the study period and included a linear time trend. Three periods were considered: the pre-case-based payment system period (from 2002 to 2004), the implementation period (from 2005 to 2008) and the post-implementation period (from 2009 to 2012). In accordance with seasonal fluctuations, random error was modelled by an autoregressive model with a parameter at lag 12.

We thus quantified the impact of the implementation as changes in the level and slope compared with the preimplementation period. SAS V.9.4 was used for all of the analyses. The threshold of statistical significance was set at P<0.05.

RESULTS
Descriptive study
The study sample contained almost 52 million admissions, accounting for all admissions with DRGs related to surgery in hospitals with >300 admissions per year. Admissions with in-hospital deaths or without linkage information were excluded and represented <5% of our admissions.

The number of admissions with surgery selected in the database increased from 4.1 million in 2002 to 5.5 million in 2012, for a total of 51.6 million admissions over the 11 years (table 1). Of the surgeries, 60% and 40% took place in profit-making private and in public or non-profit-making private hospitals, respectively. During the study period, there was a steady increase in the mean age of patients (from 48.6 to 51.3 years) and a decrease in the mean length of stay (from 4.3 to 3.0 days). The disease profile remained relatively stable, except for a slight increase in admissions in ophthalmology units.

Between 2002 and 2012, the readmission rate following admissions for surgery (figure 1) increased in both the public and private sectors: from 8.8% to 10.0% and 5.9% to 8.6%, respectively. Although the overall readmission rate was higher in public than in private hospitals (P<0.001), its increase appeared to be relatively steady in both sectors. However, this increase was significantly greater in the private than in the public sector (P<0.001).

The descriptive results underlined the disparity in readmission rates at 30 days between the different DRG groups over the study period (figure 2), in terms of both volume and evolution. In 2012, the readmission rate ranged from 2.7% for ear, nose and throat surgery to 26% for haematology and 27% for the surgical treatment of burns. Two types of surgery in particular showed a major change in the readmission rate: ophthalmology and HIV-related surgery. For ophthalmology, the readmission rate increased from 9.3% in 2002 to 16.5% in 2012 in the public sector and from 10.0% to 19.7% in the private sector. For HIV-related surgery, the readmission rate in the public sector fell from 31.4% in 2002 to 25.4% in 2012, but peaked at 39.3% in 2006, with major variations from one year to another.

The profile for the evolution of readmission rates by type of surgery also differed according to the type of hospital and surgery (figure 2). For example, the increase in the readmission rate for ophthalmology was particularly pronounced in private hospitals, rising from 10.0% in 2002 to 19.7% in 2012. Concerning other types of surgery, the readmission rate for the public and private sectors remained quite stable.

Multivariate models: study of factors associated with readmission
After adjustment for the DRG groups and morbidity, the probability of readmission at 30 days increased with time (table 2, model M0) in both the public and private sectors. We can see that the effect of the risk of readmission also increased with age and that this effect was greater in the private than in the public sector (eg, for patients aged 80 years and over, OR=1.9 in the public sector vs 5.3 in the private sector). Moreover, patients living in urban areas were slightly more at risk of readmission, with a more marked risk in small towns.

However, after excluding cases with major modifications in care practices during the period (such as ophthalmological surgery) or with low volumes of activity, the overall increase in the readmission rate found in model M0 was not retrieved for public hospitals and the readmission rate did not seem to increase with time after the implementation of the case-based payment (model M1).

Interrupted time series model
The series exhibited significant linear trends over the period (see figure 3). Rehospitalisation rates increased by 0.0170 percentage points per month in public hospitals (P<0.05) and by 0.0224 percentage points per month in private hospitals (P<0.001). However, the implementation of case-based payment was associated with a significant increase in rehospitalisation rates for private hospitals (P<0.001).

DISCUSSION
Our nationwide population-based analysis of 51.6 million hospital admissions for surgery over the 2002–2012 period found that the overall readmission rate within 30 days following discharge increased with time both in the public and private sectors, after adjustment for age, gender and comorbidities. The increase was greater in the private sector than in the public sector. However, after excluding cases with major modifications in care practices during the period, such as ophthalmological surgery, the overall increase in the readmission rate found in the previous regression logistic model was not retrieved and, for public hospitals, the readmission rate did not seem to have been influenced by the implementation of

ENT, ear, nose and throat.
case-based payment. The interrupted time series analysis confirmed that the implementation of case-based payment was only associated with a significant increase in rehospitalisation rates for private hospitals. These results suggest that hospital reimbursement is not the only determinant of readmission.

These findings contradict the results of a retrospective observational study in the USA, which found a decreased 30-day readmission rate following inpatient discharge for nine surgical specialties in the Veterans Health Administration (VHA) over a similar 10-year period (2001–2010). The fact that in France, no penalty is risked by hospitals in case of increased readmission rate may partially explain this difference. Moreover, our study included all types of surgery and specialties, including ophthalmology. We also considered all readmissions, whatever the sector, in contrast with the VHA study, in which patients having surgery at a VHA facility and then readmitted in the private sector could not be captured. In another study, comparing patients insured by Medicare before and after the implementation of the case-based payment system, the authors found that case-based payment was accompanied by a reduction in the length of stay. In parallel, the discharge mortality rate and the readmission rate did not increase. The same results were found by Kahn et al with a 24% decrease in the length of stay and an unchanged readmission rate. Another early study on the effects of implementing Medicare in the USA reported stable in-hospital mortality rates and care quality. At the same time, this stability of in-hospital mortality was put into perspective by Sager et al, who reported a significant rise in mortality at home and thus concluded that in-hospital deaths had been converted to at-home deaths in patients not covered by the new system. In Europe, it is difficult to say whether mortality rates have been affected by implementation of the case-based payment system. Studies have nonetheless shown that these systems are often accompanied by shorter lengths of stay and an increase in the number of admissions and in hospital productivity.

Cutler hypothesised that payment linked to activity could have influenced the readmission rate, given that these rates increased in hospitals with deficits and thus under financial pressure. The evolution of readmission rates was slightly different in the public and private sectors. In France, the former generally manages the most complex cases of each disease, including emergency cases. It is therefore not surprising to see a higher overall rate of readmissions in public than in private hospitals. However, comparison of the two sectors showed that the management of cataract surgery was reorganised faster in the private sector. The greater increase in readmissions in the private sector than in the public sector may be surprising, since the new pricing policy provided the least incentive for change in the private sector. The pricing policy before the case-based payment system already included payment according to activity in the private sector and readmissions were

**Figure 2** Thirty-day all-cause readmission rates after surgery according to the most frequent DRG groups, by hospital sector, all surgical procedures (France, 2002–2012). DRG, diagnosis-related group; ENT, ear, nose, and throat.
As this rise in readmissions did not seem to be only related to the pricing reform, one might wonder whether it was also related to changes in care practices. A more specific analysis of our results did not support this hypothesis. Two contrasting examples show the effect of changes in care practices on readmission rates. First consider the results from public and private hospitals across different years.

DRG, diagnosis-related group.
case of cataract surgery, nearly 500,000 surgeries per year in France. These procedures have moved from inpatient to outpatient hospitalisation with prompt recovery leading to a shortened delay between surgeries for each eye. Consequently, their increased readmission rates only reflect this shortened delay between surgeries for each eye due to the improvement in practices and not a secondary deleterious influence of hospital funding. Second, in HIV-related surgery, we observed changes in the opposite direction, with a decrease in the readmission rate, which may only reflect the improved efficacy of antiretroviral treatments leading to fewer recurrent hospitalisations. These observations suggest that to interpret these results, all changes (population, clinical practices and payment incentives) need to be considered for each group of diseases.

At the international level, the financial impact of readmissions to hospitals has led to the implementation of different policies aiming to limit such admissions as much as possible. The impact of these measures has been investigated in American studies showing that the decrease in the number of readmissions in the population studied did not stem from the implementation of such policies, but rather from the long-standing adaptation of practices of healthcare staff, as shown in our study.38 39 These results showed that an overall decrease in readmissions at 30 days has to be considered over the long term rather than as a direct and immediate result of healthcare policy. A secondary effect such as a concomitant increase in outpatient consultations needs to be considered as well.40 However, a recent study reported significant effects of such incentives, leading to decreases in readmission rates in small public-sector hospitals located in rural areas.39 In our study, we considered the place of residence of patients and not the location of the hospital as in France most hospitals are located in urban areas. We only found a slight effect of the patients’ place of residence on readmissions. We do not think that this result can be affected by the risk of ecological fallacy as we only included one aggregated variable in our logistic regression model.41

In the USA, some hospitals regularly publish their 30-day readmission rates with regard to cardiovascular or pulmonary diseases. However, a recent analysis of factors associated with readmission conducted in a cohort of patients insured by Medicare showed that not all hospitals were equally affected by readmissions.42 After adjustment for the characteristics of individual patients, hospitals recording the highest readmission rates were those with patients who were the most likely to be readmitted to the hospital due to the complexity of their illness or a low socioeconomic status.43 In our study, we could not include the socioeconomic status of patients. We are
aware that one plausible explanation for the increase in hospital readmissions could be related to the patient’s socioeconomic environment, as social and economic support at home may not be sustained and place the patient at a higher risk of readmission. Indeed, the use of readmission as a marker of complications after an initial surgical admission remains controversial. Some studies reported that almost half of readmissions were not associated with a currently assessed complication. Moreover, readmissions after surgery may be associated with new postdischarge complications related to the procedure rather than exacerbation of complications related to a prior index hospitalisation or confounding issues such as substance abuse or homelessness. Some authors believe that reduced readmission rates alone cannot be used as an indicator of care quality; their effects must be studied more globally to determine whether such reductions coincide with improved quality of life in patients.

To our knowledge, this study is the first to consider all hospital admissions resulting from all-cause readmissions within 30 days over such a long period in a given country. This study nevertheless has certain limitations. First, the global nature of readmission, chosen as an indicator in this study, can only be regarded as a partial assessment of the quality of surgical care. Other measurements should be considered, such as the mortality rate after hospitalisation. Among the readmissions identified, certain were scheduled and did not result from a complication following the first admission. It was not possible to distinguish between scheduled and unscheduled readmissions, because this information is not recorded in French claims data. This is why we decided to exclude admissions for ocular surgery in the M1 model so as to rule out most scheduled readmissions. Second, we could not compute a combined comorbidity score, as suggested by Mehta et al., from the information available in discharge abstracts. Further research is needed, first to characterise readmissions, second to study the influence of the type or the location of hospitals in greater detail, to consider readmissions after outpatient surgery, and finally to better explain the relationship between readmissions and length of hospital stay.

CONCLUSION

Our nationwide observational study is the first to consider all hospital admissions resulting from all-cause readmissions within 30 days after surgery over such a long period. It suggests that despite the slight temporary rise in readmissions during the implementation of the case-based payment system, this pricing reform does not appear to have had a significant long-lasting effect on readmissions at 30 days in the public sector. The increase in the readmission rate at 30 days after an admission for surgery appears to be related mainly to modifications in care practices, notably for cataract surgery and, second, to a structural modification associated with the ageing patient population. To interpret these results, further studies are needed to examine the influence of the different changes in populations and clinical practices on readmissions for each group of diseases.

AVAILABILITY OF DATA AND MATERIALS

The PMSI database was transmitted by the national agency for the management of hospitalisation data (ATHI number 2015-111111-47-33). The use of these data by our department was approved by the National Committee for Data Protection. We are not allowed to transmit these data.
