Support for midlife anxiety diagnosis as an independent risk factor for dementia: a systematic review

Amy Gimson,¹ Marco Schlosser,² Jonathan D Huntley,² Natalie L Marchant²

ABSTRACT

Objectives Anxiety is an increasingly recognised predictor of cognitive deterioration in older adults and in those with mild cognitive impairment. Often believed to be a prodromal feature of neurodegenerative disease, anxiety may also be an independent risk factor for dementia, operationally defined here as preceding dementia diagnosis by ≥10 years.

Design A systematic review of the literature on anxiety diagnosis and long-term risk for dementia was performed following published guidelines.

Setting and participants Medline, PsycINFO and Embase were searched for peer-reviewed journals until 8 March 2017. Publications reporting HR/OR for all-cause dementia based on clinical criteria from prospective cohort or case–control studies were selected. Included studies measured clinically significant anxiety in isolation or after controlling for symptoms of depression, and reported a mean interval between anxiety assessment and dementia diagnosis of at least 10 years. Methodological quality assessments were performed using the Newcastle-Ottawa Scale.

Outcome measure HR/OR for all-cause dementia.

Results Searches yielded 3510 articles, of which 4 (0.02%) were eligible. The studies had a combined sample size of 29,819, and all studies found a positive association between clinically significant anxiety and future dementia. Due to the heterogeneity between studies, a meta-analysis was not conducted.

Conclusions Clinically significant anxiety in midlife was associated with an increased risk of dementia over an interval of at least 10 years. These findings indicate that anxiety may be a risk factor for late-life dementia, excluding anxiety that is related to prodromal cognitive decline. With increasing focus on identifying modifiable risk factors for dementia, more high-quality prospective studies are required to clarify whether clinical anxiety is a risk factor for dementia, separate from a prodromal symptom.

INTRODUCTION

Dementia, and more specifically Alzheimer’s disease (AD), is a progressive neurocognitive disease. In the absence of any disease-modifying treatments, there is increasing focus on primary prevention to reduce the risk of its development and on early intervention to potentially slow progression. A better understanding of risk factors for dementia is therefore vital for improving therapeutic interventions. Alongside a number of well-described cardiovascular risk factors,¹ increasing evidence has highlighted the association between psychiatric illnesses and the development of late-onset dementia. Two meta-analyses have reported that a diagnosis of depression is associated with up to a twofold increase in risk.³⁻⁵ Ownby and colleagues further report that a longer interval between diagnosis of depression and diagnosis of dementia is significantly associated with an increased OR of developing dementia.³ This substantiates interpretations of depression as a risk factor for developing dementia, whereas a stronger association over shorter intervals would have been more indicative of...
prodromal symptoms. Conversely, a recent study found no association between dementia and depressive symptoms experienced more than 22 years before dementia diagnosis; however, a positive association between dementia and depressive symptoms experienced on average 11 years prior to diagnosis of dementia was reported.6,9

Although anxiety is a prevalent psychiatric disorder7 and commonly co-occurs with depression, the impact of anxiety on risk for cognitive decline and dementia has been far less studied. Anxiety symptoms are commonly experienced in the years preceding a dementia diagnosis8 and have been associated with cognitive decline and the progression from mild cognitive impairment (MCI) to AD.9–11 A recent review reported that anxiety and neuropsychiatric symptoms not reaching clinically diagnostic levels were associated with increased risk of dementia.12 The authors indicated that anxiety was likely a prodromal symptom of dementia in these community samples. This may well have been the case, particularly given the relatively short intervals between assessment of anxiety symptoms and assessment of dementia; however, this does not preclude anxiety also being a risk factor.

The association between anxiety symptoms (independent of the dementia prodrome) and dementia in later life could more easily be investigated with longer intervals between anxiety assessment and dementia diagnosis, as the studies that have investigated this association within a 5-year to 10-year interval have reported variable results.13,14 The average length of prodromal preclinical cognitive decline has been proposed to be between 5 and 6 years,15 and individuals diagnosed with MCI may progress to AD within 5 years.16 Therefore, examining studies with at least a 10-year interval between anxiety assessment and dementia diagnosis would increase likelihood that anxiety is independent from the dementia prodrome.

It is possible that anxiety symptoms meeting diagnostic threshold will have a stronger association with dementia than general symptoms because this has been shown with depression.4 To date, there has been no systematic review to investigate the association between clinically significant anxiety and dementia. The aim of this study was therefore to review the literature examining the association between clinically significant levels of anxiety and dementia risk over a longer time scale (≥10 years).

**METHODS**

This systematic review followed the Preferred Reporting Items for Systematic Reviews and Meta-analyses and Centre for Reviews and Dissemination guidance for undertaking reviews in healthcare.17

**Search strategy**

A systematic literature search of Medline, PsycINFO and Embase databases was conducted in articles published from inception to 8 March 2017 to identify articles reporting analyses of the association between anxiety (as defined by clinical diagnosis or self-report scales with a clinically significant threshold) and dementia or MCI incidence. Search terms used consisted of: (dement* OR Alzheimer* OR “mild cognitive impairment” OR MCI) AND (anx* OR “generalised anxiety disorder” OR GAD) AND (risk* OR odds), as presented in online supplementary table S1. We aimed to identify articles discussing (1) diagnosis of any type of dementia, (2) anxiety diagnosis and (3) risk of dementia. The search was restricted to human studies and those published in English. Reference lists were searched for additional relevant articles. Searches were conducted by a single reviewer (AG). An independent review of all screened articles was conducted by a second reviewer (MS). Any disagreement was resolved by consensus with a third reviewer (NM), which occurred in two cases.

**Selection criteria and article screening**

Inclusion criteria were (1) a diagnosis of anxiety or an assessment of anxiety symptoms meeting diagnostic criteria using a standardised assessment tool, excluding populations with post-traumatic stress disorder or obsessive–compulsive disorder; (2) population-based studies where anxiety is assessed at least—on average—10 years preceding final clinical assessment for dementia in line with previous meta-analyses on depression using intervals of at least 10 years;3 (3) a diagnosis of dementia using validated criteria (eg, Diagnostic Statistical Manual III–IV (DSM III–IV), International Classification of Diseases, 10th Revision (ICD-10)) and (4) late-onset dementia diagnoses (aged ≥65 years). Eligible articles were identified by performing an initial screen of titles and abstracts, followed by a full article review of those that passed screening. All retrospective and prospective studies that met these criteria were selected.

**Data extraction**

Outcome measures related to anxiety and dementia diagnosis were independently extracted by two authors (AG, MS). Disagreements were resolved through discussion. Study design, sample characteristics (including educational level and age), follow-up length, dropout rate, anxiety (including measure and baseline score where appropriate), criteria for assessing dementia and measurements of depression as a confounder (including measure and baseline score) were recorded. In cases of insufficient data, authors were contacted by email.

**Study quality**

Two authors (AG, MS) independently assessed study quality and risk of bias using the Newcastle-Ottawa Scale, which contains separate quality assessment instruments for case–control and cohort studies.

**RESULTS**

**Literature search**

The literature search detected 3509 citations, of which two were duplicates. One further paper was identified manually during reference screening. After screening titles and abstracts, 18 full-text articles were assessed.
for eligibility. Fourteen articles were excluded based on criteria described earlier (figure 1), and four studies were included in the final review.18-21

**Study characteristics**

Characteristics of the four selected studies are shown in table 1. Clinically significant anxiety was documented based on clinical diagnosis using ICD-10 criteria (n=2), the State Trait Anxiety Inventory (STAI, n=1) and a subscale of the State Trait Personality Inventory (STPI, n=1).

Gallacher et al measured anxiety using the STAI, which has a range from 20 to 80 and is a validated measure for assessing anxiety symptoms. A clinically significant cut-off of 39–40 has been proposed.23,24 Gallacher et al categorised ‘high anxiety’ as having a STAI score between 35 and 72, compared with a ‘low anxiety’ group who had a STAI score between 20 and 34. Boot et al and Zilkens et al used ICD-10 criteria to diagnose an anxiety disorder. Petkus et al assessed anxiety using state anxiety subscale of the STPI, which contains a subset of items from the STAI. Participants scoring at least 1 SD above the population mean, equating to a score of ≥25 out of 40, were categorised having ‘high anxiety’. Although there is no established cut-off for clinically significant anxiety using this scale, scores >1 SD above the population mean are likely to represent a group with a high anxiety symptom burden. After discussion among the reviewers (AG, MS, NM), we reached a consensus judgement that the study was suitable for inclusion in this review.

Dementia diagnosis was in most cases assessed using DSM III–IV (n=2) or ICD-10 criteria (n=1), although the study by Boot et al assessed dementia with Lewy bodies by clinical diagnosis using published criteria.25 Sample sizes of the studies ranged from 441 to 27 136 participants, recruited from both or either community and hospital inpatient/outpatient populations. Gallacher et al and Petkus et al conducted prospective cohort studies using a community population that excluded dementia at baseline, the latter focused on twins. Zilkens et al and Boot et al conducted matched case–control studies, which retrospectively analysed community and hospital records of individuals with dementia or case-matched controls for anxiety diagnosis and therefore did not include a cognitive assessment at baseline to exclude dementia. Zilkens et al drew controls from the electoral roll, whereas Boot et al drew them from the community-dwelling persons included in the Mayo Clinic Study of Aging. The proportion of women in each study ranged from 0% to 56.6%. Educational level was recorded for all but one study, and ranged from 55% with no qualifications to 95% with ≥9 years of education.

**Anxiety diagnosis association with dementia**

All studies included in this review found a significant increase in the number of dementia diagnoses in patients

who had a clinical anxiety diagnosis or experienced clinically significant anxiety symptoms on average at least 10 years prior to their diagnosis of dementia; Zilkens et al\textsuperscript{28}: OR=1.61 (95% CI 1.28 to 2.02), Boot et al\textsuperscript{19}: OR=7.4 (95% CI 3.5 to 16), Gallacher et al\textsuperscript{20}: OR=1.62 (95% CI 0.59 to 4.41) and Petkus et al\textsuperscript{21}: OR=1.48 (95% CI 1.01 to 2.18), respectively.\textsuperscript{18–21} On the whole, retrospective studies that looked back for lifelong diagnoses of anxiety found a stronger association between midlife anxiety and later dementia diagnosis than prospective studies investigating an association over a shorter time period. Additionally, Petkus et al\textsuperscript{21} demonstrated that the association between high anxiety and dementia diagnosis remained when they excluded participants who developed dementia within 5 years of the baseline assessment. This subsample had an average interval between baseline and dementia diagnosis of 14.7 years (SD 6.7 years). Both lend support that the associations found were independent of prodromal dementia symptoms.

Each study controlled for a range of demographic factors, and all controlled for vascular and other psychiatric risk factors (tables 2 and 3). All studies assessed and controlled for depression symptoms in their analysis. Boot et al\textsuperscript{19} found a stronger association between anxiety diagnosis alone with future dementia than either depression diagnosis alone or mixed anxiety and depression diagnosis, although the number of individuals with anxiety was markedly larger than those in the other two categories (anxiety alone n=168; depression alone n=52; anxiety and depression n=56). Although Zilkens et al\textsuperscript{28} assessed a range of psychiatric diagnoses including anxiety and depression, they did not assess their interaction. Petkus et al\textsuperscript{21} and Gallacher et al\textsuperscript{20} while controlling for depression, made no assessment of the comparative strength of relationship or their interaction.

Study quality rating

All studies included were rated highly on the Newcastle-Ottawa Scale.\textsuperscript{26} From a maximum score of 9, Boot et al\textsuperscript{19} was rated 8; and Zilkens et al\textsuperscript{28} Petkus et al\textsuperscript{21} and Gallacher et al\textsuperscript{20} were each rated 7. These studies were of similar quality to those included in a recent meta-analysis examining dementia risk estimates associated with late-life depression.\textsuperscript{4}

Three of the studies had representative samples of community populations; the fourth led by Gallacher et al\textsuperscript{20} included only men. All controlled for a range of both demographic, physical and psychological health factors. All outcomes were assessed either via secure health records or independent validation. Gallacher et al\textsuperscript{20} experienced 20% loss to follow-up, which compares favourably to the prementioned Cherbuin et al\textsuperscript{11} review, which considered studies with an attrition rate of between 4.3% and 55.46% and a review of MCI drug studies with attrition rates varying from 12% to 49%.\textsuperscript{27} Petkus et al\textsuperscript{21} did not clearly report lost to follow-up. For both case-control studies, the primary care records did not include a cognitive assessment at baseline. Therefore, pre-existing cognitive impairment before diagnosis cannot be ruled out, although long look-back periods make this less likely.

**DISCUSSION**

This systematic review found four high-quality studies that all showed a positive association between clinically significant anxiety and risk of late-onset dementia over a mean interval of at least 10 years from anxiety assessment to dementia diagnosis, even after accounting for potential confounders. This important finding provides further evidence that a common mental health condition in midlife is associated with later life neurodegenerative disorders.

Anxiety symptomatology has previously been related to dementia risk and cognitive decline, although not conclusively.\textsuperscript{10–28} A recent systematic review reported a positive association between anxiety symptoms and dementia diagnosis over a short-time interval.\textsuperscript{12} In that review, the majority of studies reported follow-up periods between 2 and 3.8 years. A single study had a follow-up time of up to 11.8 years; however, the average interval between anxiety and dementia diagnosis may have been less than 10 years, therefore, it was not included in the current review.\textsuperscript{13} Gulpers et al found stronger associations with smaller intervals between assessment of anxiety and dementia diagnosis. As a result, the authors concluded that anxiety may result from a prodromal stage of dementia, where an increase in anxiety may be due to an individual’s insight into their early subjective experience of cognitive decline.\textsuperscript{12} Given the short-time interval between assessments, Gulpers et al were unable to determine whether anxiety could also serve as an independent risk for dementia. This review reports solely articles that were not included Gulpers et al’s analyses and therefore furthers their work by providing an independent assessment of the anxiety–dementia association. Effect sizes of the studies included in this review (1.48–7.4) were comparable to the overall effect size found by Gulpers et al\textsuperscript{23} of 1.61, suggesting that the association between clinically significant midlife anxiety and later life dementia is as strong as that between late-life anxiety symptoms and dementia.

The prodromal phase of dementia can begin several years before objective dementia is manifest. In the present review, we sought to minimise the potential influence of preclinical cognitive decline by including only studies that assessed anxiety and dementia diagnoses over an extended period. Three studies\textsuperscript{18 20 21} demonstrated a mean interval of at least 10 years between the anxiety and dementia evaluations. Boot et al\textsuperscript{21} analysed participant’s lifelong medical record; however, the mean interval between anxiety and dementia diagnosis was not reported.

Findings from this review corroborate recent evidence that anxiety symptoms or diagnosis are associated with risk of MCI.\textsuperscript{29 30} These findings further complement the association between depression and dementia diagnosis,\textsuperscript{4}...
which is particularly relevant due to high levels of anxiety–depression comorbidity. Moreover, they lend support for the proposal that multiple psychiatric risk factors are implicated together as a latent risk factor for dementia.2

It has recently been suggested that a longer interval period between anxiety and dementia diagnosis may provide evidence for a common biological pathway linking anxiety, depression and dementia.20 An abnormal stress response, such as exhibited in anxiety disorders, may be associated with accelerated cellular ageing and neuroprogression (a pathological reorganisation of the central nervous system) resulting in increased

neurodegeneration, neuronal apoptosis and lowered neuroplasticity. Although glucocorticoid, inflammatory mediator and vascular disease mechanisms are hypothesised, as yet, no convincing candidate biological mechanism linking anxiety and cognitive impairment exists.

The results of this review should be interpreted in the light of their limitations. Only studies that had been published and written in English were included, which may limit extrapolation across broader populations. Retrospective studies did not examine baseline cognition and therefore cannot exclude early cognitive decline at the time of anxiety assessment; however, the length of look back, ranging from over 10 years to the first entry of an individual’s medical record, minimises the likelihood of cognitive impairment at baseline. To account for high levels of anxiety–depression comorbidity, this review included only papers discussing anxiety diagnosis alone or those that controlled for depression symptomatology. However, Zilkens et al and Boot et al cannot completely exclude overlap of these two commonly comorbid illnesses because their occurrence was ascertained from lists of diagnoses in medical records. The use of read codes in retrospective studies may have resulted in lower identification of individuals with clinically significant anxiety as a result of inconsistent entry of read codes during evaluations or of absence of clinical record for non-help seekers. Publication bias may also have influenced the studies included, as positive findings may be more likely to have been published than studies finding no association. Furthermore, results must be interpreted in the light of proposals that the prodromal AD pathophysiological processes may develop beyond 10 years before the onset of clinical symptoms.

Whether reducing anxiety in middle age would result in reduced risk of dementia remains an open question. The effect of treatment of anxiety using pharmacological and non-pharmacological therapies during midlife on later risk for dementia has not yet been investigated. Benzodiazepines, commonly used in the treatment of anxiety, have been shown to increase risk of mortality in some groups and therefore cannot be considered a measure to reduce dementia incidence in those with clinical anxiety. It is possible that diverse non-pharmacological therapies, including talking therapies and mindfulness-based interventions and meditation practices, that are known to reduce anxiety in midlife, could have a risk-reducing effect, although this is yet to be thoroughly researched.

Given the high prevalence of anxiety seen in primary care, we suggest that general practitioners could consider anxiety alongside depression as an indicator of risk for dementia. To improve the rate of earlier diagnosis of dementia, close monitoring of subtle cognitive decline in older adults with a history of anxiety, depression and cerebrovascular disease would be encouraged. This review expands our understanding of anxiety as a potentially modifiable risk for dementia. Given the limited number of studies investigating the anxiety–dementia relationship, further research is required to assess underlying mechanisms that link these disorders and to disambiguate anxiety’s potential role as a risk factor as separate from a prodromal symptom of dementia.

Moderate to severe mid-life anxiety may be linked to later life dementia

But it’s not clear whether active treatment might curb risk, say researchers

Moderate to severe mid-life anxiety may be linked to dementia in later life, suggests an analysis of the available published evidence in the online journal BMJ Open.

But as yet, it’s not clear whether active treatment could curb this risk, and whether non-drug therapies, such as mindfulness and meditation, which are known to reduce anxiety might help, say the researchers.

A mounting body of evidence suggests that mental illness may be associated with dementia in older age, but it’s not clear if it represents initial (prodromal) symptoms before the advent of fully fledged disease or if it acts as an independent risk factor.

To probe this further, the researchers trawled research databases for studies looking at the association between mid-life anxiety, in isolation or combined with depression, and the development of dementia.

Only four out of more than 3500 studies met these criteria, but they involved a total of nearly 30,000 people.

All of the studies accounted for a range of potentially influential demographic, physical, and psychological factors, and all found an association between moderate to severe anxiety and future dementia, with a gap of at least 10 years in between diagnoses.

Because the study design differed so much, pooled analysis of the data couldn’t be undertaken, but the studies were all of high quality, strengthening the findings, say the researchers.

The findings back up recent evidence pointing to a link between anxiety and risk of mild cognitive impairment, and lend weight to the known association between depression and dementia, they say.

An abnormal stress response, which is typical of moderate to severe anxiety, may speed up brain cell ageing and degenerative changes in the central nervous system, so increasing vulnerability to dementia, they suggest.

“Whether reducing anxiety in middle age would result in reduced risk of dementia remains an open question,” they write. But approaches other than anti-anxiety drugs may be worth testing, they say.

“Non-pharmacological therapies, including talking therapies and mindfulness-based interventions and meditation practices, that are known to reduce anxiety in midlife, could have a risk reducing effect, although this is yet to be thoroughly researched,” they caution.

But they suggest that given the prevalence of anxiety, it may be worth doctors considering anxiety a risk factor for dementia as well as depression.
