ABSTRACT

Objective The objective of this paper was to evaluate the structural validity and convergent validity of the first Portuguese version of the Connor-Davidson Resilience Scale (CD-RISC).

Settings The data sets come from two studies conducted in Portugal, respectively, from the Resilience Effect in Coping with Trauma (RECT) project and from the Health Impact Assessment of Employment Strategies (HIAES) project.

Participants The sample is composed of 476 participants from the RECT project and 405 participants from the HIAES project. In both projects, convenience samples were used.

Measures The original CD-RISC items were translated to Portuguese and were used in a survey along with additional psychosocial and biomedical measures.

Results Independent exploratory factorial analysis (EFA) with each of the two samples revealed that the best solution in both samples had three factors consistent with the self-efficacy, spirituality and social support factors from the original scale. A Confirmatory factor analysis using the two samples together and specifying the three factors from the EFA revealed a good overall fit and, comparatively, better fit than a model specified with the five factors from the original scale. The study of the convergent validity revealed that bivariate correlations between the three factors and validated measures of stress, life satisfaction, mental health and physical health are globally consistent with previous research.

Conclusions This study makes available to the broad Community of Portuguese Language Countries a validated measure of resilience extensively used for research and intervention. The results encourage future studies using this translated version of CD-RISC to explore further the three-factor structure found here and to test the convergent validity with new samples.

INTRODUCTION

Resilience can be described as a dynamic process of adaptively overcoming stress and adversity while maintaining normal psychological and physical functioning, and not merely the absence of psychopathology.¹ As an individual characteristic, resilience is likely influenced by external variables, such as adequate social support, that reduce risk for stress-related mental disorders by buffering the impact of stress.²

Strengths and limitations of this study

- Uses a large sample of Portuguese participants studied with rigorous data collection protocols that provide the right context to test the Connor-Davidson Resilience Scale (CD-RISC) psychometric properties in the context of the Portuguese population.
- Applies sound validated data analysis methodologies (following Green and colleagues) for testing the structural validity.
- Makes available a tested (and validated by the original CD-RISC authors) translated version to the Portuguese-speaking community.
- Has two different samples, requiring the adaptation of commonly used psychometric analysis.
- The two different samples also resulted in differences in test power for the convergent validity analysis.

In a quantitative methodological review for searching, screening and appraising resilience scales quality, the Connor-Davidson Resilience Scale (CD-RISC), the Resilience Scale for Adults and the Brief Resilience Scale received the best psychometric ratings.³

Based on the perspective that resilience is a personal quality that reflects the ability to cope with stress, Connor and Davidson⁴ developed a brief self-report scale to quantify resilience. The original version of CD-RISC has 25 self-rated items; each of them rated a 5-point scale from 0 ('not true at all') to 4 ('true nearly all the time'). Despite the absence of a proposed cut-off value, higher scores represent higher resilience. The CD-RISC was developed with participants from different settings, including the general population, primary care outpatients, psychiatric inpatients and clinical trial patients.⁴ The CD-RISC is a generic measure that can be applied to different populations since it was not developed for a specific group.⁵ The original study demonstrated solid psychometric properties, with good internal consistency and test-retest reliability, with validity being demonstrated with other measures of stress and hardness.⁴ It suggested that resilience is modifiable and can improve with treatment.

Further research on violent trauma showed that survivors who exhibit better health or less distress from the trauma are more resilient.⁶

The CD-RISC has been translated into over 50 languages and has been tested in several different contexts and specific populations: on the general population,^{7–9} post-9/11 US military veterans,¹⁰ United States Air Force,¹¹ adolescents,¹² university students,^{13–14} young adults,¹⁵ older adults,¹⁶ earthquake survivors,⁵ adolescent earthquake survivors,¹⁷ homeless youth,¹⁸ caregivers with chronic stress,¹⁹ people with spinal cord injuries,²⁰ rehabilitation patients after unintentional injury²¹ and sport performers,²² among many others.

Preliminary studies of the scale revealed that the CD-RISC has a multifactorial structure. Connor and Davidson⁴ performed exploratory factorial analysis (EFA) using the adults sample from general population. The factor analyses yielded five factors, named as *personal competence*, *high standards* and *tenacity*; *trust in one's instinct*, *tolerance of negative affect* and *strengthening effects of stress*; *positive acceptance of change* and *secure relationships with others*; *control* and *spiritual influences*. Nevertheless, the CD-RISC factor structure still needs to be clarified since subsequent studies found different factor structures.

Prince-Embury²³ suggests that the instability of factor structures might have been related to insufficient numbers of items covering various aspects of the original construct and that factor structure differences would be expected in studies of groups that varied culturally and demographically.

Therefore, the objective of this study was to evaluate the psychometric properties of the CD-RISC Portuguese version, with the aim of determining whether it can be used as a reliable and valid tool to assess Portuguese population resilience.

METHODS

The study of CD-RISC psychometric properties and convergent validity was conducted with data sets coming from two studies.

The first data set came from the Resilience Effect in Coping with Trauma (RECT) research project in Portugal, conducted at the Faculty of Psychology of the University of Lisbon. The second data set came from the Health Impact Assessment of Employment Strategies (HIAES) project in Portugal. It was approved by the National Commission of Data Protection.

Sample

The RECT project has a convenience sample of 476 participants (44% female participants) composed of master students, a technical course of medical emergency students and the general population. Participants from the HIAES project consist of 405 workers (51% female participants) at a private financial institution and is also a convenience non-probabilistic sample. Descriptive data from the two samples for general sociodemographic

variables show noteworthy differences in age and education. Regarding the age of the participants, the mean for the RECT sample was 26 (SD=6.24), while the mean for the HIAES project was 41 (SD=8.3). Concerning the education variable, the RECT project's sample was composed mostly of participants with a high school degree (58%), followed by middle school (27%) and graduate or higher (15%) degrees. The HIAES project's sample, however, had a higher percentage of participants with a graduate or higher degree (69%), followed by high school (30%) and middle school (1%) degrees.

Instruments

Besides the CD-RISC, we also collected data for a set of other measures relevant to each project objective. In this section, we only describe the CD-RISC and the measures relevant to test for convergent validity. It is important to note that different data were collected in each of the samples and, also, for different groups within each sample.

Connor-Davidson Resilience Scale

The CD-RISC⁴ is a scale developed to quantify psychological resilience and the clinical effects of the treatment of anxiety and depression. It is composed of 25 items measured using a 5-point scale (0=not true to 4=almost always true), and the original study describes five factors: the notion of personal competence, high standards and tenacity; trust in one's instincts, tolerance of negative affect and strengthening effects of stress; positive acceptance of change and secure relationships; control and, finally, spiritual influences. Despite Connor and Davidson's original study corroborating these five factors, latter studies have reported support for only one factor.⁵

Additional measures

An additional set of eight measures was collected for these two studies. More specifically, in the RECT project, the following measures were collected:

- Social Provisions Scale (SPS), an instrument that measures perceived social support.²⁴ Here we used the Portuguese version developed by Moreira and Canaipa.²⁵
- Satisfaction With Life Scale (SWLS), an instrument that measures life satisfaction based on the subjective judgement done by each person, accordingly to his own pattern of life satisfaction.²⁶ We used the Portuguese adaptation of the scale conducted by Simões.²⁷
- Perceived Stress Scale (PSS-10), a reduced version of the Perceived Stress Scale,^{28–29} an instrument used to measure the perception of stress. We used the Portuguese adaptation of the PSS-10 described by Rocha.³⁰
- Stress Vulnerability Questionnaire (23QVS), a measure of the individual's vulnerability to stress.³¹

In the HIAES project, four additional measures were collected:

- Health and lifestyle (H&LS) information regarding perceived health (measured using a single item—'How

would you classify your general health state during the last 3 months?’—and a 3-point Likert scale), the practice of physical exercise (measured using both a practice frequency and a practice quality scales) and medication consumption (Mcons) (measured using a dichotomous scale—yes vs no—for a set of 14 clinical conditions).

- Biomedical Index (BI) measured by means of blood samples, anthropometric parameters and blood pressure.
- Mental Health Inventory (MHI-5), the reduced version of the Mental Health Inventory³² that measures psychological stress and well-being using five items and a frequency scale of 1=always to 6=never. Here, we used a Portuguese adaptation of the MIH-5 described by Ribeiro.³³
- Subjective Happiness Scale (SHS), a measure of subjective happiness originally developed by Lyubomirsky and Lepper,³⁴ composed of four items responded to on a 7-point Likert scale. Again, we used a Portuguese version described by Pais-Ribeiro.³⁵

Procedure

Translation and adaptation to the Portuguese language

The CD-RISC items were translated through a process of translation and back-translation from the original American scale⁴ by specialists in psychology who were fluent in both Portuguese and English, and were finally approved by the original CD-RISC authors.

Survey procedure

For the RECT data, a survey was conducted between April 2009 and May 2010. The questionnaires were administered in paper-and-pencil format. This was done either face-to-face or administered in a classroom context. The CD-RISC was completed by 421 participants, while the additional convergent validity measures were completed by 55 participants.

For the HIAES data, a survey was conducted between November 2012 and June 2013. The survey had two parts: the first part of the survey, with sociodemographic information and H&LS, MHI-5 and SHS scales, was completed electronically, while in the second part, the participants completed the CD-RISC in paper and pencil format. Additionally, for a subsample of 260, anthropometric measures and blood samples were collected.

All the participants from both research projects were informed of the investigation and gave their signed informed consent. The participants were not involved in the design and planning of the study.

Structural validity

The main objective of this paper was to study the structural validity of the Portuguese version of the CD-RISC. We followed Green and colleagues¹⁰ procedure where an EFA was used to test the factorial structure of the original 25-item five-factor solution version of the CD-RISC, and afterwards, a confirmatory factor analysis (CFA) was

used to compare a proposed solution based on the EFA results with Connor and Davidson’s original one. We note that this methodology used by Green and colleagues is particularly suited for our type of data. More specifically, this methodology allows understanding of the specific behaviour of the items in each of the two samples and only then to test the factorial structure of the scale with the complete sample.

Two independent EFAs were conducted in each one of the two data sets. In this analysis, the following criteria were taken into account. First, to determine the number of factors, we considered the criterion of an eigenvalue higher than 0.7. Second, for the interpretation of the items in each factor, the rotational oblimin solutions were considered, since the factors are expected to correlate with each other. Additionally, for an item to be held for a particular factor, communalities should be higher than 0.09, loadings should be equal to or higher than 0.32, and also cross-loadings should be lower than 0.32.³⁶ Finally, the resulting items in a factor were tested for internal consistency using Cronbach’s alpha.

Following the EFA, two CFAs were conducted using the complete sample to test and compare both the proposed solution as specified by EFA and the original 25-item five-factor solution. The statistical quality of the models was assessed using two sets of measures. First, the overall goodness of fit was measured considering the following criteria: Standardized Root Mean Square Residual (SRMR) and Root Mean Square Error of Approximation (RMSEA) lower or equal to 0.08, Comparative-Fit Index (CFI) and Tucker-Lewis Index (TLI) higher or equal to 0.90. Additionally, the localised areas of strain were measured with the following criteria: standardised residuals lower or equal to 2.58 and general modification index analysis lower or equal to 4.

Both analyses used pairwise deletion for missing data. Results were compared with a mean replacement method and no differences were found.

Convergent validity

Another aim of the present paper was to provide data for the convergent validity of the CD-RISC. The convergent validity is a form of validation that tests for the association between a construct measured by a scale and other measures that theoretically relate to this construct.^{37 38} For the convergent validity of the CD-RISC, variables used in the survey of the HIAES and RECT projects were selected and bivariate correlations were computed. First, due to the sample dimension and the characteristics of the variables studied, only correlations with a p value equal to or lower than 0.01 were considered statistically significant.³⁹ Second, for the interpretation, we considered correlation values inferior to 0.20 as weak correlations, correlation values between 0.20 and 0.60 as moderate correlations, and correlation values higher than 0.60 as strong correlations.

Patient and public involvement

The patients and the public were not involved in the conception, design or interpretation of this study.

RESULTS

Structural validity

Exploratory Factorial Analysis

The first set of EFAs was conducted on each data sample, forcing the 25-items to the original five-factor solution and, following Karairmak⁵ and Burns and Anstey,¹⁵ to three-factor and one-factor solutions. The results on both data set indicated that none of the solutions replicated corresponding results. In fact, the factor structure for the five-factor and three-factor solutions did not hold, and for the three solutions tested, several items revealed low communalities, low loadings and cross-loadings in both samples. In line with this, items 5, 11, 12, 14, 17, 20 and 23 were excluded because of systematic problems in the different solutions. A second set of EFAs was conducted with the 18 items for each data sample. Once the original five-factor and three-factor solutions could no longer be interpreted, we used the scree plot to choose the best solution. The results on both data sets showed that the best solution had three factors, but items 22 and 25 still revealed problematic. A final set of EFAs

was conducted with the 16 items. Results showed that the best solution in both samples had three factors with 37% and 31% of explained variance, respectively (tables 1 and 2). Factor 1 was the most representative factor, composed of 11 items and explained 20% and 16% of variance, respectively, and an alpha of 0.82 and 0.76. This factor, which we labelled *self-efficacy*, describes individuals' beliefs about not only their personal competence while dealing with challenging demands but also their ability to exercise control over their own functioning. Factor 2 was composed of three items and explained 9% and 8% of variance, respectively, and an alpha of 0.71 and 0.67. This factor was named *spirituality* and evaluates specific aspects of spirituality, namely, the belief that life has a purpose and that spiritual forces can influence earthly events. Finally, factor 3 was composed of two items and explained 8% and 7% of variance, respectively, and an alpha of 0.53 and 0.44. This factor refers to the perceived *social support* and evaluates how people perceive their reliance on others for emotional and functional support. We note that the alphas for self-efficacy and spirituality are above 0.7. Also, for social support, once there were only two items, we used bivariate correlations. Here, the results showed a moderate association between the two items.

Table 1 Factorial weights of the 16 items on each of the three factors and respective explained variance for the Resilience Effect in Coping with Trauma sample

Items/explained variance	Communalities	Self-efficacy	Spirituality	Social support

10	0.18	0.33	0.19	0.19
9	0.52	0.08	0.72	0.00
21	0.37	0.09	0.60	0.07
3	0.36	−0.06	0.59	0.13
2	0.59	0.09	0.06	0.76
13	0.35	0.21	0.14	0.54
Variance explained	–	16%	8%	7%
Alpha	–	0.76	0.67	0.44*
M (SD)	–	3.03 (0.40)	2.47 (0.84)	3.24 (0.67)
n	–	405	405	405

*Correlation for the two items, $p < 0.05$.

A descriptive analysis of the three subscales showed that the average results for self-efficacy were above the midpoint of the scale and had small SDs on both RECT and HIAES samples, 2.92 (SD=0.54) and 3.03 (SD=0.40), respectively. The same applied to the average results and SDs of the spirituality subscale, 2.64 (SD=0.91) and 2.47 (SD=0.84), respectively, and of the social support subscale, 3.14 (SD=0.83) and 3.24 (SD=0.67), respectively.

Confirmatory factorial analysis

CFA was conducted to test the model specified by EFA and to compare this model with the one suggested by Connor and Davidson's original five-factor solution. Considering the meaning of both the proposed three-factor solution and the original five-factor solution, in both cases, the CFAs were computed, allowing for factors to correlate among themselves.

A preliminary analysis of the frequency distributions and statistics for skewness and kurtosis of CD-RISC showed severe negative asymmetry of the data in most of the 25 items. To reduce the impact of the data distributions on the model computations, we log transformed all the data (note that the data were previously transformed to eliminate 0 values by adding a constant, and afterwards all the results were inverted). The asymmetry of the resulting log transformed frequency distributions for the 25 items

was significantly reduced and consequently used in the CFA.

The results for the proposed 16-item three-factor solution revealed a good overall fit, $\chi^2 (101) = 368.64$, $p < 0.001$; SRMR=0.05, RMSEA=0.06 (0.05, 0.06), CFI=0.90 and TLI=0.89. The analysis also showed that few standardised residuals were higher than 2.58, and, similarly, few modification indexes were above 4. Finally, all items were highly correlated with their factors, with all correlations between 0.40 and 0.77 and all p values < 0.001 .

The results for the original 25-item five-factor solution revealed a moderate overall fit, with both CFI and TLI measures slightly below the criteria, $\chi^2 (263) = 1219.08$, $p < 0.001$; SRMR=0.06, RMSEA=0.07 (0.06, 0.07), CFI=0.82 and TLI=0.79. Additionally, the analysis also showed several standardised residuals above the criteria, and, similarly, several modification indexes were above 4. All items were significantly correlated with their factors (all p values < 0.001), but correlations ranged between a weak 0.20 and a strong 0.70. Overall, the proposed 16-item three-factor solution had better performance in the CFA.

Convergent validity

Six of the eight measures used to test the convergent validity (ie, SPS, SWLS, PSS-10, 23QVS, MHI-5 and SHS) were tested for the structural validity on their

Table 3 Descriptives (mean, SD and sample size) of the measures used to test the convergent validity

	M	SD	n
SPS	8.75	9.36	53
SWLS	24.72	5.26	54
PSS-10	14.51	5.49	55

Met	0.12	0.32	260
Card	3.31	2.03	450
MHI-5	68.91	18.97	405
SHS	5.24	1.08	405

23QVS, Stress Vulnerability Questionnaire; BI, Biomedical Index; Card, index for cardiovascular risk; H & LS, health and life style; Mcons, medication consumption; Met, metabolic syndrome; MHI-5, Five-Item Mental Health Inventory; Pact, physical activity; Phea, physical health; PSS-10, 10-Item Perceived Stress Scale; SHS, Subjective Happiness Scale; SPS, Social Provisions Scale; SWLS, Satisfaction With Life Scale.

unidimensional versions (table 3). Results from all levels of explained variance were above 40%, and all Cronbach alphas were above 80. The sole exception to these results is the 23QVS, with a somewhat lower explained variance of 23% and an alpha of 0.76. Additionally, for the H&LS, we considered a single item on physical health (Phea) and two indexes, one on physical activity (Pact) using the average of the frequency of Pact and of commitment to the Pact, and an index on Mcons, consisting of the sum of the answers for Mcons regarding 14 clinical conditions. Finally, for the BI, we computed an index to identify the presence of metabolic syndrome (Met) using the recommendations of the European Society of Cardiology (<http://www.escardio.org>) and an index for cardiovascular risk (Card) based on the norms of the Portuguese Society of Cardiology (www.spc.pt).

Bivariate correlations were computed between each one of the three subscales, computed based on the 16 items in the CD-RISC and each of the eight measures described above and used to test the convergent validity (table 4). The self-efficacy factor showed a significant negative association with the two measures of stress considered: perceived stress ($r=-0.32$) and vulnerability to stress ($r=-0.34$). There were positive correlations between the self-efficacy factor and two additional variables, namely, subjective happiness ($r=0.31$) and mental health ($r=0.35$). Although moderately, the self-efficacy factor as a significant and negative correlation with Phea ($r=-0.17$) and Mcons ($r=-0.13$) ('Note that Phea is measured using

a single item where the higher the value the lower the Phea reported').

The spirituality factor showed only a marginal significant correlation with the vulnerability to stress measure ($r=0.25$).

The social support factor showed a moderate significant correlation ($r=0.48$) with the SPS.²⁴ The social support factor is also correlated with the SHS ($r=0.30$) and the MHI-5 ($r=0.26$) scales. There was a marginal significant negative correlation between social support and vulnerability to stress ($r=-0.24$). The social support factor correlates significantly with Met ($r=-0.13$) and Card ($r=-0.10$), although the magnitude of both correlations is weak.

DISCUSSION

The objective of this paper was to evaluate the structural validity and the convergent validity of the first Portuguese version of the CD-RISC. Despite the importance of this construct, to date, there is no validated scale to measure resilience in the Community of Portuguese Language Countries (n.d.),⁴⁰ estimated to be more than 270 million people. Resilience is a fundamental element of mental health, health assets, capabilities and positive adaptation. It enables people to both cope with adversity and reach their full potential, and influences a wide range of outcomes at individual and community levels, including

healthier lifestyles, better Phea, improved recovery from illness, fewer limitations in daily living, higher educational attainment, greater productivity, employment and earnings, better relationships with adults and with children, more social cohesion and engagement and improved quality of life.⁴¹ It is not a surprise that resilience has been extensively measured and used to understand individual and social phenomena.

The results do not replicate the original five-factor structure; instead, the results suggest a three-factor structure with self-efficacy, spirituality and social support dimensions represented. Although this result is not consistent with the original proposal from Connor and Davidson, it is consistent with more recent studies.^{5 42} Consistent with this, the variability of factor structures found in CD-RISC has been documented and owed to methodological variations, idiosyncratic samples and, importantly, to cross-cultural factors.⁴³ We also note that, similar to the original study and to some of the following research, self-efficacy is the factor that explains the greatest variance of the original items. Still, although the results are important to understand the construct of resilience and how CD-RISC works as an instrument measuring this construct in a Portuguese sample, we note that the resulting scale should not be regarded as an improved version. In fact, we consider that improved usage of this scale would come from prior testing of the factorial structure of the original 25 items and comparison with the results of this paper and similar.

The results from the validation are, with one sole and justifiable exception, consistent with evidence from the literature. The negative association we found between the self-efficacy factor and the measures of stress is consistent with the idea that people with high-efficacy beliefs are able to overcome obstacles and focus on opportunities, and are more able to perceive stressful situations as challenging rather than as problematic events.⁴⁴ The positive correlations between self-efficacy and happiness and satisfaction with life are consistent with the findings in the literature where self-efficacy beliefs may regulate positive and negative emotions. In this sense, people with higher self-efficacy beliefs are less distressed and feel more capable of dealing with problematic situations.⁴⁵ Recent studies have found that self-efficacy is indeed positively correlated with happiness⁴⁶ and satisfaction with life.⁴⁴ Although moderately, the negative correlation between the self-efficacy factor and the measures of Phea and Mcons constitutes an extension of the findings where self-efficacy is associated with increased health and life satisfaction.

The positive correlation we found between the spiritual factor and the vulnerability to stress is consistent with Connor and colleagues⁶ study with survivors of violent trauma, where spirituality is proposed as a coping strategy to deal with higher post-traumatic stress disorder scores. Still, the fact that spirituality does not relate with any other variables is not consistent with the literature, where previous studies have successfully established correlations between spirituality and happiness⁴⁷ and

between spirituality and life satisfaction.⁴⁸ The absence of effects can be a result of the low statistical power due to the small sample size in the RECT sample. In fact, a post hoc power analysis showed that the power to detect a significant correlation of 0.20 at 0.05 in our sample is only 0.28.

Interestingly, the positive correlation we found between the social support and the SPS²⁴ is the only significant correlation of the SPS, which supports the assumptions that this factor is a specific dimension of resilience. The positive correlations we found between the social support factor and the SHS and MHI-5 scale are consistent with the findings in the literature showing the strong impact of social support on happiness, especially from closer social circles.⁴⁹ For instance, in a study with survivors from a natural disaster, the authors found that predisaster happiness and postdisaster social support were protective against the negative effect of the hurricane on survivors' postdisaster happiness.⁵⁰ The negative correlation we found between social support and vulnerability to stress is consistent with the findings in the literature, in which it is becoming increasingly consensual that the lack of social support is an important risk factor in dealing with stressful and adverse life events.⁵¹ We found negative correlations between social support and Met and Card. Despite some of the literature describing a conflicting relation between social support and Phea,⁵² it appears that social support is negatively associated with cardiovascular death and that it protects against recurrent events, the existing research suggests the predictive relation between social support/social networks and incidence of disease, specifically cardiovascular disease.

In summary, regarding the self-efficacy factor, we found associations with perceived stress, vulnerability to stress, subjective happiness and mental health. Additionally, we also found associations with perceived Phea and Mcons, what we consider to be an extension of the findings relating self-efficacy with health and life satisfaction. Regarding the spirituality factor, we found only an association with vulnerability to stress. This result is not consistent with the literature where spirituality has been related with stress, happiness and life satisfaction. As mentioned, the absence of effects here is likely due to low test power. Finally, regarding the Social Support Scale, we found an association with the SPS, subjective happiness, mental health and vulnerability to stress. Additionally, we also found an association with the two BIs used, specifically, Card and Met. Resilience, through its self-efficacy component, showed a protective effect on the extent of myocardial infarction by affecting the inflammatory response.⁵³ Emotional vitality, as part of healthy psychological functioning, may protect against risk of coronary heart disease (CHD).⁵⁴ Resilience could have life-saving effects. Prevention and intervention in CHD not only must involve measures to reduce psychological distress but also should focus on promoting positive emotions.

Applications for the Portuguese version of the CD-RISC

Our study extends the literature that has provided support on the importance of the construct of resilience and, more particularly, on the use of CD-RISC as a reliable measure of this construct. In fact, using a robust psychometric method, we replicated more recent studies describing three main dimensions of resilience. Additionally, using a vast array of validated measures, we also showed how these factors were associated with scales, indexes and even behavioural measures in a way that was consistent with the literature. Importantly, these associations support the distinctiveness of the three factors, with different factors relating, as expected, with some different convergent measures. Take for instance the strong correlation between the social support factor and the SPS, and the stronger correlations between the self-efficacy factor and both stress and vulnerability to stress. A curious finding here is the specific association of self-efficacy with Phea and Mcons and the association of social support with two BIs, Card and Met.

Future directions and research limitations

Our study extends the possibility to measure and investigate resilience in Portuguese communities using a rigorously validated scale. Future studies with this community can explore further the three-factor structure of the CD-RISC and test for the convergent validity with new samples. A limitation of the current paper is the difference in test power between the two samples used to do the convergent validity. This is particularly important because the low test power sample (from the RECT project) included important and unique validation measures and because the spirituality scale did not replicate entirely the findings in the literature. Finally, and considering both research and practice, future studies with the Portuguese communities can follow the factorial structure found and validated. These studies can, again, provide additional support to the theoretical and practical relevance of resilience and its dimensions as measured by the CD-RISC.

Acknowledgements We thank Carla Crespo and Maria Violante Doria for their support in the Connor-Davidson Resilience Scale translation process, and also all the colleagues and institutions that supported us in the data collection (namely, Joana Carreiras and Susana Oliveira). We thank Professor Jonathan Davidson for his helpful feedback throughout this process of paper construction.

Funding The Health Impact Assessment of Employment Strategies project was funded by the Office of the High Commissioner for Health followed by the General Health Direction.

Competing interests None declared.

Patient consent for publication Not required.

Ethics approval This research project was reviewed by the Ethical Committee of the University of Lisbon, Faculty of Psychology, which granted authorisation to perform these studies. The second data set, which came from the Health Impact Assessment of Employment Strategies (HIAES) project in Portugal, was approved by two institutional ethical committees, the Ethics Committee for Health of the National Institute of Health Doutor Ricardo Jorge public institute and the Ethics Committee for Health of the Lisbon/North Hospital Centre of Faculty of Medicine of the University of Lisbon. This research was conducted under the Helsinki declaration code of ethics. Ethics approval was obtained for the scientific use of the data in both studies. This involves the usage of the data and publication of the results in thesis and scientific journals.

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement Statistical codes and data sets are available from the figshare repository (<https://doi.org/10.6084/m9.figshare.7111676.v1>).
