ABSTRACT

Objective Traumatic brain injury is now a major contributor to the global healthcare burden. Migraine is another debilitating disease with a global health impact. While most researchers agree that traumatic brain injury is a risk factor for migraine, whether migraine is a risk factor for traumatic brain injury still remains under debate. We therefore aimed to investigate whether migraine was a risk factor for developing traumatic brain injury.

Study design Retrospective population-based cohort study.

Setting Data for people who had been diagnosed with migraine were retrieved from Taiwan's National Health Insurance Research Database.

Participants We identified 7267 patients with newly diagnosed migraine during 1996–2010. The migraineurs to non-migraineurs ratio was set at 1:4 to enhance the power of statistical tests.

Primary and secondary outcome measures We used multivariate Cox proportional hazard regression models to assess the effects of migraines on the risk of traumatic brain injury after adjusting for potential confounders.

Results The overall traumatic brain injury risk was 1.78 times greater in the migraine group compared with the non-migraine group after controlling for covariates. Additionally, patients with previous diagnoses of alcohol-attributed disease, mental disorders and diabetes mellitus had a significantly higher traumatic brain injury risk compared with those with no history of these diagnoses.

Conclusions This study of a population-based database indicated that migraine is a traumatic brain injury risk factor. Greater attention to migraine-targeted treatment modalities may reduce traumatic brain injury-related morbidity and mortality.

INTRODUCTION

Globally, an estimated 10 million people suffer a traumatic brain injury (TBI) event every year.¹ The combined incidence of TBI-related emergency department visits, inpatient hospital admissions and mortalities reached 823.7 per 100 000 in 2010.^{2–3} Additionally, TBI is a major cause of long-term disability in young adults^{1–3–4} and can negatively affect quality of life in patients, their friends and relatives, and even the general population.^{5–7} By 2020, TBI is projected to be the third largest contributor to the global healthcare burden.^{8–10} Therefore, an

Strengths and limitations of this study

- This is the first observational cohort study using a Chinese population-based data set in Taiwan to clarify whether migraine is a risk factor for traumatic brain injury.
- The major strength of this research is the use of a large population-based database, which could provide sufficient statistical power.
- The secondary database used in the study was encrypted to protect citizen's privacy.
- Self-reported pain scores for rating migraine were not recorded in the database.
- The results of the research need to be interpreted with caution in different ethnicities.

improved understanding of pathophysiology of TBI and its risk factors is needed to minimise the risk of TBI-related morbidities and mortalities in high-risk groups for TBI.

Migraine is a debilitating disease that has a significant impact on worldwide health.¹¹ According to the primary criteria for headache, a migraine headache is defined as a moderate to severe unilateral headache that may be accompanied by photophobia, vomiting or nausea, and visual symptoms. Migraines can also compromise cognition, vestibular function, emotions and social behaviours.^{12–13} Thus, the debilitating effects of migraine can make patients prone to TBI. Most studies of associations between TBI and migraine have focused on causal relationships between TBI and post-traumatic migraine. While most researchers agree that TBI is a risk factor for migraine,¹² whether migraine is a risk factor for TBI remains unclear. For example, although Gordon *et al* reported that migraine is a risk factor for TBI, the coding procedures used in their study were not available for further validation. Another problem is that the study results vary because data reviewed by Gordon *et al* were collected from questionnaires. Additionally, the psychopathology of TBI has not been precisely ascertained.¹⁴ Therefore, Gordon *et al* provide little information about the

association between migraine and TBI. Current policies for TBI care and prevention can be highly burdensome for patients, their relatives and society. Given the limited availability of epidemiological data for TBI, the objective of this study was to conduct a nationwide study of patients with migraine to clarify the association between TBI and migraine.

METHODS

Data sources

Methods

Database

This population-based cohort study was performed using computerised records from the Taiwan National Health Insurance Research Database (NHIRD), a large encrypted secondary organised collection of data maintained by the Taiwan national healthcare system. More than 99% of the population (23.74million) in Taiwan have been covered by the single-payer National Health Insurance since its implementation in 1995. The government entrusts the Taiwan National Health Research Institute with maintaining this database by continuously collecting relevant registration and claims data for the purpose of academic research. Therefore, the NHIRD contains comprehensive medical records of literally the entire population of Taiwan for the past two decades. This retrospective cohort study analysed a subset of the NHIRD, the Longitudinal Health Insurance Database 2010, which contains detailed data for 1 million individuals sampled from the primary NHIRD. International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes were used to identify and classify diseases.^{15 16} The study was performed in accordance with the Declaration of Helsinki guidelines.

Study population

The migraine cohort in this study included 7267 patients diagnosed with migraine (ICD-9-CM code 346) in 1996–2010 and aged 18 years or older. To maximise case ascertainment, the analysis was limited to patients with a record of ≥ 1 migraine diagnosis during inpatient service or ≥ 2 migraine diagnoses during outpatient visits; additionally, only records in which an ICD-9-CM code for migraine had been assigned by a neurologist were used. The date of the first migraine diagnosis was defined as the index date. Migraine with aura, migraine without aura and unspecified migraine were defined according to ICD-9-CM codes 346.0, 346.1 and 346.9, respectively.¹⁷ A TBI (ICD-9-CM code 800803–804 and 850–854; operation codes 01.23, 01.24, 01.25, 01.31, 01.39 and 02.01)^{15 18–21} was defined as a record of two or more TBI diagnoses in outpatient visits or one or more TBI diagnoses in inpatient admissions. Cases of TBI were further categorised into three groups based on the severity of injury. A TBI was classified as severe if the patient required surgery in the course of inpatient treatment; a TBI was classified as moderate if the patient required hospitalisation but not

surgery; a TBI was classified as mild if the patient did not require inpatient treatment.^{15 22}

The exclusion criteria were diagnosis of TBI before or on the index date, age younger than 18 years and incomplete information. The date of migraine diagnosis was defined as the date of the first diagnosis of migraine. An identical ‘pseudo date of diagnosis’ was assigned to matching control cases, which was the date of diagnosis in matched subjects.

The migraine to non-migraine ratio was set at 1:4 to obtain a sufficient number of TBI cases and to enhance the power of statistical tests used in stratified analyses. Each patient in the migraine cohort was matched by gender, age and year of migraine diagnosis with four persons in the non-migraine cohort obtained in the same period. Therefore, 29 068 cases were enrolled in the non-migraine cohort. Figure 1 shows a flow chart of the study procedure.

Outcome and comorbidities

Both the migraine and the control cohorts were followed up until the end of 2010, withdrawal from insurance or TBI diagnosis, whichever occurred first. Baseline comorbidities which were ascertained from ICD-9-CM codes in claims records included diabetes mellitus (ICD-9-CM code 250), hyperlipidaemia (ICD-9-CM code 272), hypertension (ICD-9-CM codes 401–405), coronary artery disease (ICD-9-CM codes 410–414), liver cirrhosis (ICD-9-CM code 571), tobacco use disorder (ICD-9-CM code 350.1), obesity (ICD-9-CM code 278), mental disorders (ICD-9-CM codes 290–319) and alcohol-attributed diseases (ICD-9-CM codes 291.0–9, 303, 305.0, 357.5, 425.5, 535.3, 571.0–3980.0 and V11.3). At follow-up, income-related insurance payments and urbanisation indices were used as proxy measures of individual socioeconomic status. Insurance premiums were classified into three groups as stated by monthly insurance payments: less than NT\$20 000; NT\$20 000–NT\$40 000; and more than NT\$40 000.^{23 24} Urbanisation index was categorised as high (metropolitan cities), medium (small cities and suburban areas) and low (rural areas).²⁵

Statistical analyses

The clinical characteristics and categorical demographics of the study cases were analysed by the χ^2 test to compare between the migraine and non-migraine cohorts. Kaplan-Meier method was used to estimate cumulative incidence of TBI, and the differences between the curves were calculated by two-tailed log-rank tests. For patients with migraine, survival was calculated until the study endpoint (31 December 2010), until the date of inpatient hospital treatment or until the date of an outpatient visit for TBI, whichever occurred first. The two cohorts were compared using the TBI incidence rates estimated in 1000 person-years. Mean age and follow-up time (years) were compared between the two cohorts by using Student's t-test and Wilcoxon rank-sum test. If the proportional hazards assumption was satisfied, univariable

Figure 1 Flow diagram summarising the process of enrolment. LHID, Longitudinal Health Insurance Database.

and multivariable Cox proportional hazard regression models were performed to calculate HRs and 95% CIs for TBI.^{26–29} All statistical tests were performed using Statistical Analysis Software V.9.4 (SAS Institute), and adopted a two-tailed significance level of 0.05.

Patient and public involvement

The patients and the public were not involved in the research.

RESULTS

Baseline characteristics of patients with and without migraine

In table 1, the baseline demographic characteristics and comorbidities of the study participants are shown. In the migraine group, 73.84% patients were female. Compared with the non-migraine group, the migraine cohort had significantly higher percentages of patients with diabetes mellitus (31.64% vs 16.61%; $p<0.001$), hypertension (50.14% vs 25.04%; $p<0.001$), hyperlipidaemia (50.28% vs 25.76%; $p<0.001$), coronary artery disease (8.52% vs 2.49%; $p<0.001$), liver cirrhosis (48.20% vs 25.14%; $p<0.001$), mental disorders (31.48% vs 11.34%; $p<0.001$), obesity (4.66% vs 2.22%; $p<0.001$), alcohol-attributed disease (4.14% vs 2.13%; $p<0.001$) and tobacco use disorder (4.32 vs 0.65; $p<0.001$). During a median observation time of 2.8 years, 3.74% (272) of the patients with migraine had TBI (IQR=1.2–5.4). The TBI incidence in the migraine cohort was significantly ($p<0.001$) higher than that in the non-migraine cohort (797 with TBI out of

29 068 age and gender-matched controls (2.74%)) during a median observation time of 5.3 years (IQR=2.6–8.4). The median duration of follow-up of TBI was significantly shorter in the migraine group (2.8 years) compared with the non-migraine group (5.3 years).

TBI incidence and risk

Table 2 shows the results of the stratification analysis, including TBI incidence and HRs by age, gender and comorbidity. During the follow-up period, TBI developed in 3.74% (272) of the patients with migraine and in 2.74% (797) of the non-migraine patients. The overall TBI risk was 1.78 times greater in the migraine group compared with the non-migraine group (5.35 vs 1.86 per 1000 person-years, respectively) after adjusting for age, gender, income, urbanisation and related comorbidities (hypertension, diabetes mellitus, hyperlipidaemia, coronary artery disease, liver cirrhosis, mental disorders, obesity, alcohol-attributed disease and tobacco use disorder).

In both cohorts, gender-specific analyses showed that the incidence of migraine per 1000 person-years was higher in men than in women (6.46 vs 4.97, respectively, in the migraine cohort; 2.59 vs 1.60, respectively, in the non-migraine cohort). The migraine group had a significantly higher TBI risk in both genders (adjusted HR=1.94, 95% CI 1.60 to 2.36 for women; adjusted HR=1.48, 95% CI 1.13 to 1.95 for men). In all age groups, the migraine cohort consistently showed a higher incidence of TBI, and the incidence rate increased with age. Age-specific

Obesity	339 (4.66)	645 (2.22)	<0.001
Tobacco use disorder	314 (4.32)	188 (0.65)	<0.001
Alcohol-attributed disease	301 (4.14)	619 (2.13)	<0.001

risk comparisons also showed that, for all age groups, the migraine cohort had a significantly higher TBI risk compared with the non-migraine cohort. Without considering comorbidities, TBI risk was lower in non-migraine patients than in patients with migraine. However, the TBI risk in patients with migraine with comorbidity was lower than the TBI risk in non-migraine patients with comorbidity.

In [figure 2](#), the cumulative incidence of TBI between the migraine and non-migraine groups is compared using the Kaplan-Meier curves at the 15-year follow-up. The Kaplan-Meier curves revealed a significantly higher cumulative incidence of TBI in the migraine cohort compared with the non-migraine cohort (log-rank test, $p<0.001$).

Risk factors for TBI in patients with migraine

[Table 3](#) shows the Cox regression analysis results, which revealed that risk factors for TBI in the migraine group were alcohol-attributed disease (adjusted HR=2.45; 95% CI

1.67 to 3.60), mental disorders (adjusted HR=1.42; 95% CI 1.11 to 1.81) and diabetes mellitus (adjusted HR=1.46; 95% CI 1.15 to 1.85). Notably, female gender and high income had protective roles against TBI in these patients.

[Table 4](#) compares TBI risk in different migraine types. For all migraine types, the migraine group had a significantly higher TBI risk compared with the non-migraine group.

[Table 5](#) compares incidence rates and HRs for various outcomes between patients with and without migraine. Compared with the non-migraine cohort, the migraine cohort faced 149% increase in the risk of mild TBI, 36% increase in the risk of moderate TBI and 263% increase in the risk of severe TBI after adjustment of covariates. Migraine had the strongest association with severe TBI.

DISCUSSION

To the best of our knowledge, this study is the first to investigate TBI risk in a large cohort of patients with

Table 2 Incidence and HRs of traumatic brain injury by demographic characteristics, comorbidity and follow-up duration among patients with or without migraine

§Patients with any examined comorbidities, including hypertension, diabetes mellitus, hyperlipidaemia, coronary artery disease, liver cirrhosis, mental disorders, obesity, tobacco use disorder and alcohol-attributed disease, were classified as the comorbidity group.

TBI, traumatic brain injury.

migraine in Asia. The main finding of this study is that migraine is a potential risk factor for subsequent TBI. Specifically, the migraine group had a 1.78-fold higher TBI risk compared with the non-migraine control group after adjusting for age, income, gender, urbanisation and related medical comorbidities. The association between migraine and TBI risk was significantly higher in younger populations compared with older populations analysed in this study. Additionally, TBI risk was significantly higher in patients who had a previous diagnosis of alcohol-attributed disease, mental disorders or diabetes mellitus compared with those with no history of these diagnoses. Notably, patients in the migraine group were prone to severe TBI.

Previous studies have similarly shown that migraine is associated with TBI. For example,³⁰ a multivariate analysis in an exploratory study by Gordon *et al* reported that independent risk factors for concussion include migraine, young age and male gender. Notably, their study analysed

the publicly available set of microdata collected by the Canadian Community Health Survey of 270 patients (age, 12–24 years) who had a history of sports-related concussion. The data set was remarkably complete, for example, it had less than 0.5% missing data and no missing age or gender data for migraine and TBI. However, the study only analysed self-reported data for migraine history and did not provide information regarding the cause–effect relationship between migraine and TBI. The patients in the Canadian Community Health Survey were also considerably younger than those in our current study and were not matched by gender. Furthermore, the sample was not sufficiently representative of the general population or of true clinical status.¹⁴ In 2009, Lau *et al* reported a study of the prognostic value of self-reported symptoms and neurocognitive performance after concussion in a group of 108 football players aged 13–19 years. Fifteen participants reported a preinjury migraine headache history, and 23 participants said they had a history

Figure 2 Cumulative incidence of traumatic brain injury among patients with migraine and the control cohort.

Table 3 Cox regression model: significant predictors of TBI after migraine

Variables	Adjusted HR*	(95% CI)	P value
Alcohol-attributed disease	2.45	(1.67 to 3.60)	<0.001
Mental disorders	1.42	(1.11 to 1.81)	0.005
Diabetes mellitus	1.46	(1.15 to 1.85)	0.002

TBI, traumatic brain injury.

of either migraine or other headache types. However, no causal relationship was established.³¹

Moreover, reported causes of migraine include failure of cerebral ion homeostatic regulation and excess release of excitatory amino acids caused by cortical spreading suppression and depolarisation.³² Breakdown of ion homeostasis caused by cortical spreading suppression is the primary mechanism of neuronal damage after TBI. Although migraine and TBI share some common pathophysiologicals,^{32 33} the exact mechanism of the association between preinjury migraine and TBI is not well understood.

Although the exact mechanisms underlying the relationship between migraine and TBI are unclear, several risk factors for TBI in patients with migraine are established. First, migraine is associated with lower cognitive function. For example, a 2014 study by Gil-Gouveia *et al* systematically reviewed evidence of decline in cognitive function during a migraine attack. Their review showed that migraine usually causes deficits in executive functions such as attention, working memory and processing speed.³⁴ Another nationwide study by Chuang *et al*

reported that migraine is associated with an increased risk of future dementia after adjusting for comorbidities. The migraine and non-migraine cohorts in their study included 33 468 and 133 872 patients, respectively, and had similar distributions of age and gender. The authors concluded that the migraine cohort had a 1.33-fold higher dementia risk compared with controls.³⁵ Finally, migraine is associated with low cognitive function and impaired executive control functions,³⁶ which can increase the risk of accidents or TBI by increasing risky behaviour or carelessness.³⁷

A second cause of increased TBI risk in patients with migraine is their increased likelihood of psychiatric comorbidities,^{38–40} which have been identified as a TBI risk factor.^{41 42} For example, a review of a general population of patients by Antonaci *et al* found that patients with migraine have a higher risk of affective and anxiety disorders compared with those without migraine. Another line of research suggests that migraine is associated with bipolar disorder. One hypothesis is that people with mental disorders have lower than normal attention, concentration and reaction times, all of which contribute to increased TBI risk.^{38 43 44} Third, chronic migraine headache causes postural instability and vestibulopathy, which increase the risk of falls; falls are the major cause of TBI in the USA.⁴⁵

The main strength of this study is the use of a population-based data set, which included nearly all cases of migraine and TBI treated in Taiwan during the study period, to demonstrate an association between migraine and TBI risk. The cohort study design with controls and the large sample size also enabled stratification of analyses by the severity of TBI and time. Since data collection was not affected by recall bias, the analyses had sufficient statistical power to identify significant differences between the migraine cohort and non-migraine cohorts.

However, several weaknesses of this study are noted. The first limitation is potential coding errors. Like most administrative databases, coding information is directly generated from administrative discharge claims data designed for billing purposes. Clinical physicians are subject to oversights in documentation and entering diagnostic codes. However, the validity of true diagnoses was

Table 4 Incidence and HRs for TBI stratified by the different types of migraine

TBI, traumatic brain injury.

increased by limiting the analyses to patients whose claims data included at least two outpatient diagnoses. In some rare cases of TBI, the patient may only visit the emergency department without undergoing further follow-up at the outpatient department. In Taiwan, the medical treatment is easy to access at a low cost. Therefore, patients with TBI always receive initial treatment at the emergency department and undergo regular follow-up visits at the outpatient department. Second, some data needed to determine the severity of migraine or TBI were not available in this study, including the mechanism of TBI (ie, falls, motor vehicle accidents, sports injuries and violence),⁴⁶ the International Headache Society criteria, results of brain CT (location, size or type), associated injuries and Glasgow Coma Scale.⁴⁷ Third, TBI events might have been overestimated in patients with migraine with comorbid psychiatric disorders, who consume more health resources compared with those without comorbid psychiatric disorders. Comorbid patients would be expected to seek medical services even when the severity of TBI is relatively low.³⁸ Additionally, most inhabitants of Taiwan are ethnic Chinese; further studies are needed to investigate the association between migraine and TBI risk in other ethnicities.

In conclusion, this population-based cohort study indicated that patients with migraine have significantly higher than normal risk of developing TBI. Additionally, migraine mostly affects the development of severe TBI relative to other grades of TBI. Register-Mihalik *et al*⁴⁸ have shown the baseline headache associated with increased incidence but also severity of concussion. Thus, migraine may be a poor contributor to TBI. However, further detailed studies are needed to explore the underlying mechanisms of this association. The association between change in brain ion homeostasis or excitatory amino acids and severity of advanced neuronal damage needs further elucidation. Migraine-targeted treatment modalities may help reduce morbidity and mortality associated with TBI.

¹¹Department of Surgery, School of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan

Contributors Y-YL and Q-RW were equal contributors in this study. HQ and Y-JS were equal contributors in this study. The authors' individual contributions are outlined as follows. Substantial contributions to conception and design: Q-RW, Y-YL, Y-JS, HQ, LZ, M-KW, C-LZ and C-HW. Drafting and revising the article critically for important intellectual content: Q-RW, Y-YL, Y-JS, HQ and C-HW. Final approval of the version to be published: Q-RW, Y-YL and C-HW.

Funding This study was supported by grants from the Kaohsiung Medical University Hospital (KMUH105- 5M17 and KMUH106- 6T09).

Disclaimer The funders had no role in the study design, data collection and analysis, design to publish or preparation of the manuscript.

Competing interests None declared.

Patient consent for publication Not required.

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement All data relevant to the study are included in the article.

Open access This is an open access article distributed in accordance with the Creative Commons Attribution Non Commercial (CC BY-NC 4.0) license, which permits others to distribute, remix, adapt, build upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited, appropriate credit is given, any changes made indicated, and the use is non-commercial.
