ABSTRACT

Objectives Numerous studies reported that achieving near-normal glycated haemoglobin (HbA1c) levels in patients with diabetes may delay or even prevent vascular complications. However, information regarding the impact of non-optimal HbA1c control on adverse health outcomes in an Arab population is unknown. The aim of this study was to estimate the fraction of deaths and potential years of life lost (PYLL) attributable to non-optimal HbA1c control among Emirati men and women with diabetes in the United Arab Emirates (UAE).

Design A retrospective cohort study.

Setting This study was conducted in outpatient clinics at a tertiary care centre in Al Ain, UAE, between April 2008 and September 2018.

Participants The sample comprised of 583 adult UAE nationals, aged ≥18 years, with diabetes. Overall, 57% (n=332) of the study participants were men and 43% (n=251) were women.

Exposure Non-optimal HbA1c control, defined as HbA1c ≥6.5%.

Primary outcome measure All-cause mortality, defined as death from any cause.

Results At the end of the 9-year follow-up period, 86 (14.8%) participants died. Overall, up to 33% (95% CI 2% to 63%) of deaths were attributable to non-optimal HbA1c control among patients with diabetes mellitus (DM). Stratified by sex, the adjusted fraction of avoidable mortality was 17% (95% CI –23% to 57%) for men and 50% (95% CI 3% to 98%) for women. Both deaths and PYLL attributable to non-optimal HbA1c control were higher in women compared with men.

Conclusions Up to one-third of all deaths in adult UAE nationals with DM could be attributed to non-optimal HbA1c control. Effective sex-specific interventions and healthcare quality-improvement programmes should urgently be implemented.

INTRODUCTION

The WHO estimates that type 2 diabetes mellitus (DM) was the seventh leading cause

Strengths and limitations of this study

- This is the first long-term observational cohort study to estimate the fraction of deaths and potential years of life lost attributable to non-optimal glycated haemoglobin control in adult United Arab Emirates (UAE) men and women with diabetes.
- The diabetes status was determined at baseline and could have changed during the follow-up period, which might have impacted our estimate of the population-attributable fraction (PAF).
- This study was conducted in outpatient clinics of a single tertiary care hospital; therefore, our results may not be applicable to the general population in the UAE.
- Data on other confounding variables that could have impacted study outcomes, such as socioeconomic status, dietary habit and physical activity, were unavailable.
- The CIs for the PAF were wide, indicating that the sample size was relatively small.

of death worldwide in 2016.¹ The global prevalence of DM among adults has more than doubled over the past four decades and continues to rise.¹

The United Arab Emirates (UAE) has witnessed substantial economic development since the discovery of oil half a century ago. This increased prosperity has altered the health profile in the UAE with improved access to modern healthcare services and universal health insurance for its citizens.² In the UAE, life expectancy at birth is slowly improving and the most recent estimates for men and women were 76.4 and 80.2 years, respectively, in 2017.³ However, this dramatic economic transformation has also led to major lifestyle changes among its residents. Sedentary lifestyles and unhealthy dietary

habits have resulted in the UAE having one of the highest prevalence of DM worldwide with an age-adjusted prevalence of 17.3% in 2017.⁴

DM substantially increases the risk of cardiovascular disease (CVD), renal disease, visual impairment and peripheral neuropathy,^{5–7} as well as the risk of premature death.⁸ The WHO estimates that around half of all global deaths in patients with DM aged under 70 years are attributable to poor glycaemic control,¹ while the proportion of all deaths due to DM among UAE residents aged under 60 years was 69.1%.⁴

There is strong evidence that achieving near-normal glycated haemoglobin (HbA1c) levels in DM significantly reduces morbidity and mortality.⁹ However, despite this evidence, less than half of patients with DM achieve their HbA1c target. A UAE study, in 2015, reported that only 38% of adult patients with DM had achieved the HbA1c target of <7% and that poor glycaemic control was higher in females and patients aged >60 years.¹⁰ This result was similar to a US study, conducted more than a decade ago, which reported that only 34% of patients with DM had achieved optimal glycaemic control.¹¹

The proportion of deaths avoided if patients had achieved the HbA1c target can be quantified by measuring the impact of a specific risk factor on public health, and is described as the population-attributable fraction (PAF).¹² Since no evidence exists regarding the impact of non-optimal HbA1c control on mortality among Arab patients with diabetes, the aim of this study was to estimate the fraction of deaths and potential years of life lost (PYLL) attributable to non-optimal HbA1c control in UAE nationals with DM.

METHODS

This was a retrospective cohort study based on data obtained from electronic medical records of UAE nationals with DM, registered at outpatient clinics at Tawam Hospital in Al Ain, UAE, between 01 April 2008 and 31 December 2008. Tawam Hospital is a tertiary care hospital, which provides healthcare services to approximately 19 000 adult UAE nationals with DM of Al Ain, the second-largest city in the Emirate of Abu Dhabi, UAE. We included consecutive patients aged ≥18 years who had serum HbA1c level ≥6.5%, a diagnosis established by a physician or been receiving medications for DM (eg, sulfonylurea, thiazolidinedione, dipeptidyl peptidase-4 inhibitor, biguanide or insulin). Patients with incomplete data on serum HbA1c levels and missing history of DM at baseline were excluded (figure 1). Annual follow-up data were obtained between the baseline visits in 2008 and 30 September 2018.

Definitions of clinical variables and outcomes

Hypertension (HTN) was defined as systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥90 mm Hg or the use of antihypertensive medications.¹³ Fasting lipid profiles were measured using

Figure 1 Flow chart of the study population. HbA1c, glycated haemoglobin.

standard methods and the UniCel Dx-C-800 Synchron Clinical System (Beckman Coulter, Brea, California, USA). Dyslipidaemia was defined as the presence of one or more of the following: triglyceride ≥1.69 mmol/L, total cholesterol ≥5.17 mmol/L, low-density lipoprotein cholesterol ≥3.36 mmol/L, high-density lipoprotein cholesterol <1.03 mmol/L or documented treatment with lipid-lowering medications.¹⁴ Body mass index (BMI) was calculated as weight (kg) divided by height (m) squared and obesity was defined as BMI ≥30 kg/m². Smoking history was positive if there was a current or history of smoking of tobacco. Patients were considered as having CVD if they had a diagnosis of coronary heart disease (angina, prior myocardial infarction, angioplasty of the coronary arteries or coronary artery surgery), cerebrovascular accidents or peripheral vascular disease. History of cancer was defined as an established diagnosis of cancer of any type. Chronic kidney disease (CKD) was defined as an estimated glomerular filtration rate <60 mL/min/1.73 m².¹⁵ HbA1c was assessed by the medical laboratory department at Tawam Hospital using an automated analyser (Integra 400 Plus; Roche Diagnostics GmbH, Mannheim, Germany). Non-optimal HbA1c control was defined as HbA1c ≥6.5%.¹⁶

Mortality data were collected retrospectively during the follow-up period until 30 September 2018. Death was defined as death from any cause and was confirmed through the review of medical records and death certificates. Time to event was calculated for each patient as the difference between the date of the inclusion into the study and the date of death, or the date of the last outpatient clinic visit, whichever occurred first.

Statistical analysis

Data were expressed as mean ± SD or percentages. The baseline characteristics were compared by sex using the

independent samples t-test for continuous variables and Fisher's exact test (two-tailed) for categorical variables.

For this analysis, we estimated Cox proportional hazards regression models adjusted for age (continuous), sex, HTN, dyslipidaemia, cancer, smoking, CVD, CKD, obesity and DM medications to estimate HRs and 95% CI for the association between non-optimal HbA1c control and mortality. The assumption of proportionality was met on the basis of log-log plots.

The main exposure of interest was non-optimal HbA1c control. The outcomes of interest were death and PYLL. PYLL was calculated by subtracting the average age of death from the average life expectancy (for UAE nationals in 2017³), and then by multiplying this number by the number of non-optimal HbA1c control-attributable deaths.

We estimated the PAF associated with non-optimal HbA1c control using the attributable fraction package for censored survival data in R software.¹⁷ The PAF for HbA1c $\geq$ 6.5% was adjusted for age (continuous), sex, HTN, dyslipidaemia, cancer, smoking, CVD, CKD, obesity and DM medications. The PAF was then used to calculate deaths and PYLL that could be averted if HbA1c control was optimal. The proportion of mortality cases and PYLL that could have been prevented if all patients had optimal HbA1c control was indicated by a positive PAF. Conversely, a negative PAF is the proportion of mortality

cases and PYLL that could have additionally occurred if patients had optimal HbA1c.

All statistical analyses were performed using R software V.3.5.2 (The R Foundation, Vienna, Austria) and IBM SPSS software V.25. All p values were two-tailed, and <0.05 were considered statistically significant.

Patient and public involvement

There was no patient or public involvement in the design and conduct of the study.

RESULTS

Baseline characteristics

The analysis in the current study included 583 subjects with DM (figure 1), with a median follow-up of 9.1 years (IQR 8.1–9.7 years). Approximately 57% of the study participants were men (table 1). The mean age of participants at baseline was 58.4 years (SD 12.4 years) and the mean $\pm$ SD HbA1c was 7.85% $\pm$ 1.93%. Approximately 84% (487/583) of patients were on medications for DM. Of these treated patients, only 23% (113/487) had optimal HbA1c control. The baseline characteristics stratified by sex are presented in table 1. Men were older at baseline; more frequently had a history of smoking, dyslipidaemia and CVD; but less frequently had a history of obesity than women. HbA1c at baseline was significantly higher in

men than in women ($p<0.001$). There were no significant differences by sex in non-optimal HbA1c control at baseline ($p=0.138$).

Mortality and PYLL

At the end of the follow-up period, 86 (14.8%) deaths occurred. The multivariable-adjusted HR for all-cause mortality comparing patients with and without optimal HbA1c control was 1.79 (95% CI 0.95 to 3.39). The multivariable-adjusted PAF for deaths due to non-optimal HbA1c control was 33% (95% CI 2% to 63%) (table 2). Overall, 28 (95% CI 2 to 54) deaths could have been prevented if the HbA1c of all participants in the study had been maintained in the optimal range. Similarly, 190 (95% CI 12 to 363) PYLL could have been prevented if the HbA1c was optimal in all patients.

When stratified by sex, the confounder-adjusted fraction of avoidable mortality was 17% (95% CI -23% to 57%) for men and 50% (95% CI 3% to 98%) for women. Shown in figures 2 and 3, respectively, are the deaths and PYLL attributable to non-optimal HbA1c control, by age category and sex. The avertable deaths were higher for the

Figure 2 Deaths attributable to non-optimal HbA1c by age and sex. HbA1c, glycated haemoglobin. **Figure 3** PYLL attributable to non-optimal HbA1c by age and sex. HbA1c, glycated haemoglobin; PYLL, potential years of life lost.

older age groups in both men and women. In women, the avertable PYLL was higher in the 40–54 years age group; however, in men, the PYLL was higher in the 55–64 years age group. Overall, both deaths and PYLL attributable to non-optimal HbA1c control were higher in women than in men.

Extrapolating from our cohort to the approximately 155 000 adult UAE nationals with DM⁴ and assuming that this population is comparable to our study population, based on our results, we estimated that approximately 22 900 deaths would have been observed within 9 years among the Emirati population with DM. Of these total deaths, around 7600 deaths would be attributable to non-optimal HbA1c control.

DISCUSSION

This long-term observational cohort study suggests that among adult Emiratis with DM, about one-third of all deaths over the 9-year period could have been prevented with optimal HbA1c control. By extrapolating our results to the UAE national population with DM, we estimated the burden of non-optimal HbA1c control among Emiratis. In the approximately 155 000 adult UAE nationals with DM,⁴ this would correspond to about 840 deaths that could have potentially been avoided annually.

There is only one comparable longitudinal study in the international literature that estimated the attributable risk associated with HbA1c levels for all-cause mortality in patients with DM. The cardiometabolic Valencian (ESCARVAL-RISK) study conducted on a large general-practice cohort of Spanish patients with DM reported the PAF associated with uncontrolled diabetes as 13.6% (95% CI 4.0% to 23.9%) for all-cause mortality.¹⁸ This estimate was much lower than what was observed in our study. This difference may be explained by different population characteristics and follow-up time between the two studies (patients with CVD were excluded from the ESCARVAL-RISK study and had a follow-up of 3.3

years vs 26% with a history of CVD and a follow-up of 9.1 years in our study).

To the best of our knowledge, the PAF linked to non-optimal HbA1c control by sex has not been previously reported. We found that more deaths could have been avoided in women with non-optimal HbA1c control than in men. Moreover, in our study, the PAF associated with uncontrolled diabetes was not statistically significantly contributing to the risk of mortality in men. Most previous studies have supported the claim that women with DM are at higher risk for morbidity and mortality compared with men with DM.^{19–22} A meta-analysis of patients with DM reported that women were 50% more likely to die of fatal coronary heart disease than men.²³ It is not known why women with DM are at increased risk for morbidity and mortality compared with their male counterparts. One explanation is that CVD risk factors affect women more than men. The Strong Heart Study showed that between women with and without DM, the differences in levels of several CVD risk factors were greater than differences found in men with and without DM.²⁴ Another possible explanation is that women with diabetes are less likely than men to have CVD risk factors aggressively treated.²⁵ In addition, results from a Korean study on patients with DM showed that compared with men, women were less likely to achieve optimal HbA1c control after 1 year of treatment.²⁶ Our findings demonstrate possible sex differences in mortality among Emirati patients with poorly controlled DM and support the urgent need for developing sex-specific tertiary prevention strategies in the UAE.

In our study, patients with DM had a moderate glycaemic control with a mean±SD HbA1c of 7.85%±1.93% at baseline and only approximately 19% of them had optimal HbA1c target of <6.5%. These results are consistent with other studies carried out in neighbouring Middle Eastern and Western countries,^{27–30} indicating that poor glycaemic control in patients with DM is a serious issue worldwide. A study conducted among 651 patients with DM in Saudi Arabia showed that close to 21% of patients had optimal HbA1c control.²⁷ A nationwide French survey on 4930 patients with DM reported that the mean HbA1c was 7.6%±1.6% and in 27% of patients, the HbA1c level was ≤6.5%.²⁹ Possible reasons for this failure may be multifactorial, such as poor compliance with medications, and therapeutic inertia on the part of healthcare providers. A recently published systematic review reported that the delay in the intensification of therapy following an HbA1c measurement above the target level was longer than 1 year.³¹ Furthermore, the increasing prevalence of multimorbidity among patients often complicates the management of DM,³² and may also contribute to suboptimal diabetes management. It is well-known and widely accepted that achieving optimal HbA1c target levels in patients with DM, as outlined in current clinical guidelines,^{16 33 34} decreases the risk of vascular complications and improves the life expectancy.^{6 9} Therefore, future studies, to investigate effective and efficient solutions in

improving glycaemic control in patients with DM, should be high on the list of priorities for all decision-makers involved in DM care.

Strengths and limitations

To the best of our knowledge, this is the first long-term observational cohort study to estimate the fraction of deaths and PYLL attributable to non-optimal HbA1c control in UAE national men and women with DM. The PAF assesses potential health benefits through risk factor control and disease prevention. It is a helpful instrument for effective health communication that may increase both public and healthcare professionals' awareness of DM. It may also aid in decreasing the risk of mortality with the implementation of healthcare quality-improvement programmes by key stakeholders.

This study has several limitations. First, the DM status was determined at baseline and could have changed during the follow-up period, which might have impacted our estimate of the PAF. However, transitions from diabetes to non-diabetes status are rare.³⁵ Second, this study was conducted in outpatient clinics of a single tertiary care hospital; therefore, our results may not be applicable to the general population in the UAE. Third, the changes in HbA1c levels and DM treatment over time were not assessed and could have affected the study results. In addition, data on other confounding variables that could have impacted the study outcomes, such as the socioeconomic status, dietary habits and physical activity, were unavailable. Finally, the CIs for the PAF were wide, indicating that the sample size was relatively small; however, our study in an Arab population with a long follow-up duration gives us a better picture of the high burden of diabetes in the Middle East, where data on associated poor glycaemic control is sparse. Additional large multicenter studies are needed to confirm our results.

CONCLUSION

In conclusion, non-optimal HbA1c control contributed to one-third of all deaths in patients with DM in the UAE. This places a significant burden on the health of Emiratis with DM, their families and the health systems. Effective interventions, such as the training of DM care teams on sex-specific prevention strategies, periodic monitoring of DM and improving patients' education, are essential to increase adherence to management guidelines and should be implemented without delay.
